

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

LECTURES

ON INFLAMMATION,

(Delivered in the Theatre of the Royal College of Surgeons of England).

BY JAMES PAGET,

Professor of Anatomy and Surgery to the College.

LECTURE IV.

Degenerations and diseases of the lymph-products of inflammation.—General account of degenerations, as normal changes to which all living parts are prone; their relations to the other modes of natural nutrition, and their purposes; their difference from diseases.—Varieties of normal degenerations.

Characters of these degenerations when they affect inflammatory products in their several stages of development.—Degenerations of fibrine: its withering, liquefaction, disintegration, fatty, calcareous, and pigmental degenerations.—Degenerations of lymph-corpuscles; their withering, degeneration into granule-cells, and disintegration; their calcareous and pigmental degenerations: formation of various pus-cells, and their subsequent degenerations, as observed in the contents of chronic abscesses.—Degenerations of adhesions, and other examples of fully organised lymph.—Diseases of the products of inflammation.

In the last lecture a general history was given of the chief developments of the lymph exuded in the inflammatory process. I propose now to tell a corresponding history of its degenerations; and herein to describe what appear to be the transitions from the ordinary forms of lymph in its primary state,—its fibrine and its corpuscles,—to those many lower forms enumerated as molecular and granular matter, as pus-cells, granule-cells, inflammatory globules, and the rest. I said that, for the development of lymph produced in inflammation, it is requisite that the inflammation shall have ceased, and the conditions of healthy nutrition be restored. In the failure of this event, if the inflammation continue, or the due conditions of nutrition be in any way suspended, then, instead of development, degeneration may ensue. And this may happen in any of the stages

of formation which I described in the last lecture: it may happen alike to the rudimentary fibrine, or to the earliest lymph-cell, or to either, in any part of its progress to complete development.

Allow me first to illustrate generally what is to be understood by degeneration, as distinguished from disease, and to point out some of the larger principles which the very active inquiries of late years made enable us to enunciate concerning degenerations.

The usually admitted modes of normal operation of the nutritive processes are three—namely, development, growth, and maintenance or assimilation.* The accepted meanings of these terms are known; and I need only say concerning them that the maintenance of a part by assimilation must not imply the maintenance of an unchanged state, but a series of minor progressive changes slowly worked in the part, and consistent with that exercise of its functions which is most appropriate to the successive periods of its existence.

But to these three we should add, as another normal method of nutrition, the process of natural degeneration, such as occurs in advanced life. To degenerate and die is as normal as to be developed and live: the expansion of growth, and the full strength of manhood, are not more natural than the decay and feebleness of a timely old age,—not more natural, because not more in accordance with constant laws, as observed in ordinary conditions. As the development of the whole being, and of every element of its tissues, is according to certain laws, so is the whole process regulated, by which all that has life will, as of its own workings, cease to live. The definition of life that Richat gave is, in this view, as untrue as it is illogical. Life is so far from being “the sum of the functions that resist death,” that it is a constant part of the history of life that its exercise leads naturally to decay, and through decay to death.

Of the manner in which this decay or degeneration of organisms ensues we know but little. Till within the last few years the subject of degenerations was scarcely pursued: and, even of late, the inquiries, which ought to range over the whole field of living nature, have been almost exclusively limited to the human body. The study of development has always had precedence in the choice of all the best workers in physiological science. They who have devoted many years of laborious

* Lectures on Nutrition, in MEDICAL GAZETTE for 1847.

thought and observation to the study of the changes by which the living being is developed from rudiment to perfection, have given fewer hours to the investigation of those by which, from that perfection, it naturally descends into decay and death. Almost the only essays at a general illustration of the subject have issued in the ridiculous notion that, as the body grows old, so it retrogrades into a lower station in the scale of animal creation. The flattened cornea is supposed to degrade the old man to the level of the fish; while the *arcus senilis*, by a fancied correspondence with an osseous sclerotic ring, maintains him in the eminence of a bird; his dry thick cuticle makes him like the pachydermata; and his shrivelled spleen approximates him to the humility of the mollusk. One can only commend such day-dreams to the modern supporters of the doctrine of transmutation of species; and they might, indeed, form an appropriate supplement to their scheme, if they would maintain that, in these latter days, our species is destined to degenerate into lower and yet lower forms, descending through the grades by which, in by-gone times, it ascended towards its climax in humanity.

One cannot but wonder at the comparative neglect with which wiser men than these philosophers have treated a study so full at once of interest and of importance as this of the natural degeneration of the body. It could not be without interest to watch the changes of the body as life naturally ebbs,—changes by which all is undone that the creative force in development had achieved,—by which all that had been gathered from the inorganic world, impressed with life, and fashioned to organic form, is restored to the masses of dead matter,—to trace how life gives back to death the elements on which it had subsisted,—the progress of that decay through which, as by a common path, the brutes pass to their annihilation, and man to immortality. Without a knowledge of these things our science of life is very partial, very incomplete. And the study of them would not lack that peculiar interest which appertains to inquiries into final causes; for all the changes of natural decay, or degeneration, in living beings, indicate this purpose and design—that, being gradual approximations to the inorganic state of matter, they lead to conditions in which the elements of the body, instead of being on a sudden and with violence dispersed, may be collected into those lower combinations in which they may best rejoin the inorganic world; they are such, that each creature may be said to die through that series of changes which may best suit it, after death, to discharge its share in the

economy of the world, either by supplying nutriment to other organisms, or by taking its right part in the adjustment of the balance always held between the organic and the inorganic masses.

Nor would the student of the design of these degenerations do well to omit all thought of their adaptation, in our own case, to the highest purposes of our existence. When, in the progress of the “calm decay” of age, the outward senses, and all the faculties to which they minister, grow dim and faint, it may be on purpose that the Spirit may be invigorated and undisturbed in the contemplation of the brightening future; that, with daily renewed strength, it may free itself from the encumbrance of all sensuous things, or retain only those fragments of thought or intellectual knowledge which, though gathered here on earth, yet bear the marks of truth, and, being Truth, may mingle with the truth from Heaven, and form part of those things in which Spirits of infinite purity and knowledge may be exercised.

Moreover, the changes of natural degeneration in advanced life have a direct importance in all pathology, because the right understanding of them may guide us to the interpretation of many anomalies which, while they occur in earlier life, we are apt to call diseases, but which are only premature degenerations, and are to be considered, therefore, as defects, rather than as perversions, of the nutritive process, or as diseases only in consideration of the time of their occurrence.*

In this view, it will be a great help to our knowledge of disease if we can determine and arrange all the changes that mark the progress of natural decay or degeneration, i. e. the decay of old age, or of naturally abrogated functions. They seem to be these—1. Wasting or withering; the latter term may imply the usually coincident wasting and drying of a tissue. 2. Fatty degeneration, including many of what have been called granular degenerations. 3. Earthy degeneration, or calcification. 4. Pigmental degeneration. 5. Thickening of primary membranes.

Of each of these let me cite one or two examples.

Of *withering*, or wasting and drying, which is perhaps the commonest form of

* One can here have in view only the cases in which the degeneration affects the whole, or some considerable part of an organ; for it is very probable that some of the degenerations which we see *en masse* in the organs of the old, or in the seats of premature defect of nutrition, are the same as occur naturally in the elementary structures of parts, previous to their being absorbed and replaced, as it were by one particle at a time, in the regular process of nutrition.

atrophy, we have abundant instances in the emaciation of old age; in which, while some parts are removed by complete absorption, others are only decreased in size, and lose the succulency of earlier age.

Of the *fatty degeneration* in senility, we have the best proofs, as to its general occurrence, in the increasing obesity which some present at the onset of old age, and in the general fact that there is more fatty matter in all the tissues, and most evidently in the bones, than there is in earlier life; while, for local senile fatty degeneration, we find the *arcus senilis*, or fatty degeneration of the cornea, according to the interesting discovery by Mr. Canton,* and the accumulating fatty or atheromatous degenerations of arteries.

The *calcareous degeneration* is, in old age, displayed in the gradually increasing proportion of earthy matter in the bones; in the extension of ossification to cartilages, which, in all the period of vigour, had retained their embryonic state; and in the increasing tendency to earthy deposits in the arteries, and other parts.

The *pigmental degeneration* has its best instances in the gradually accumulating black pigment spotting and streaking the lungs; in the slate or ash-colour which is commonly seen in the thin mucous membranes of the stomach and intestines of old persons;† and in the black spotting of the arteries of some animals, in which pigment seems to hold the place of the fatty degenerations so usual in our own arteries.‡

Of the *thickening of primary membranes* we have indications in the usual thickening of the tubules of the testes, and, I think, of some other glands, as their function diminishes in old age; in the opaque white thickening of the primary or inner membrane of nearly all bloodvessels; and in the thickening of the walls of cartilage-cells in some forms of ossification. To this, also, we have a strong analogy in the thickening of the cell-walls of the heart-wood of plants.

Such are the changes which, singly or in various combinations, constitute the most evident degenerations of old age in man. Their combinations give rise to numerous varieties in their appearance, such as, *e. g.*, the increase of both fatty and earthy matter in old bones; the fatty degeneration and wasting of the pulmonary membrane in the

emphysematous lung; the dry, withered, and darkly tinged epidermis; the coincident fatty and calcareous deposits in old arteries. But I need not dwell on these, nor on the conditions which determine the occurrence of one rather than another mode of degeneration; for these I cannot tell. Let me rather observe that, taken singly, all the changes I have enumerated display certain characters, which should be present in every process that may be justly called a degeneration, and distinguished from disease. In all true degenerations these, or most of these, following characters should concur:—

First, and before all others, it should be a change naturally and usually occurring, in one or more parts of the body, at the approach of the natural termination of life, or, if not then beginning, yet then regularly increasing.

2. It should be a change in which the new material is of lower chemical composition, *i. e.*, is less remote from inorganic matter than that of which it takes the place. Thus, *e. g.*, fat is lower than any nitrogenous organic compound, and gelatine lower than albumen, and earthy matter lower than all these.

3. In structure, the form should be less developed than that of which it takes the place: it should be either more like inorganic matter, or less advanced beyond the form of the mere granule or the simplest cell. Thus the approach to crystalline form in the earthy matter of bones, and the crystals in certain old vegetable cells, are characteristic of degeneration; and so are the granules of pigment and of many granular degenerations, and the globules of oil that may replace muscular fibres or the contents of gland-cells.

4. In function, the part should have less power in its degenerate than in its natural state.

5. In its nutrition, it should be the seat of less frequent and less active change, and without capacity of growth, or of development.

Such are the characters of degenerations; and there are many things which show that the assumption of these characters is to be ascribed to a defect, not to a perversion, of the vital force, or of the conditions of nutrition.

Thus (a) these are all apt to occur in a part of which the functions are abrogated: a motionless limb wastes or becomes fatty as surely as an old one does. (b) They often occur, too, in parts that fail to attain the development for which they seemed to be intended. Thus, *e. g.*, fatty degeneration usually ensues in the cells of unfruitful Graafian vesicles.* (c) They bear also a certain

* Lancet, April 1850.

† It is remarkable that this accumulation of pigment should be occurring in any set of organs while pigment is disappearing from other parts; such as the hair.

‡ I have seen a similar black pigmental degeneration of the minute arteries of the human brain.

general analogy to the changes that ensue in some of the materials that are habitually excreted from the body; in the construction or composition of which materials one seems to have an instance of the gradual superposition of the ordinary or imitable processes of chemistry. (d) Again, they display living parts tolerating the presence and incorporation of inorganic or dead matter; fat being commonly infiltrated about degenerate cells and membranes, and earthy matter with it, even in the crystalline form. (e) And, lastly, and perhaps most clearly, the origin of degenerations from defective, rather than from perverted, conditions of nutrition, appears in the fact that one, at least, of them may be produced artificially. The fact observed by Dr. Quein,* that the fatty degeneration of muscular fibre is closely imitated when healthy dead muscle is placed in dilute acid, suggests, as the formation of adipocere did to Dr. Williams,† that, during life, the change of the protein-compound, which leaves the residuum of fatty matter, is one of common, that is, of imitable chemistry. Now we may be sure that where this chemistry prevails, there the forces or conditions of life are in defect.

From the whole, we may safely hold that, as the changes to which the several tissues are naturally prone in old age are the results of defect, not of perversion, of the nutritive process, so are the corresponding changes when they happen in earlier life; although, through their appearing prematurely, they may in this case bear the features of disease. Therefore, we should be prepared to separate from the catalogue of diseases all those changes in which we find the marks of degeneration alone; for the distinction of degeneration from diseases must be an essential, though often it may be an obscure, one. The one is natural, though it may be premature; the other is always unnatural: the one has its origin within, the other without, the body: the one is constant, the other as various as the external conditions in which it may arise: finally, to the one we are prone, to the other only liable.

I will now proceed to describe what, in accordance with the foregoing observations, appear to be the chief degenerations of inflammatory products. As I have said,

the degeneration may begin in any period of the formation of the lymph, as well in its rudimental as in its fully organised state; and that which determines for degeneration rather than development seems always to be the continued suspension of the conditions of nutrition.

The following appear to be the chief degenerations of the fibrine of lymph, or of the materials derived from its earliest stages of development:—

1. It may wither—wasting, and becoming firmer and drier, passing into a state which Rokitsansky* has designated *Aorwy*. One sees the best examples of this change of fibrine in the vegetations on the valves of the heart, or in the large arteries, when they become yellow, stiff, elastic, and nearly transparent.† The fibrine may, in this state, show no marks of development into tissue, but may have all the simplicity of structure of ordinary fibrine, being only drier and more compact. A similar character is nearly acquired when lymph is deposited over a lung which is extremely compressed in empyema, or in hydrothorax.‡ The tough dry lymph that here forms the greyish layer over all the lung is not always developed, though it may adhere firmly: it is withered, wasted, and dried (as the lung itself may be) in consequence of the compression.

2. Fibrine is subject to a degeneration which we may compare with fatty degeneration. In the coagula, or solid parts of effusions, that are found in the lower forms of inflammation, or in very unhealthy persons, the fibrine is usually not clear and uniform, and filamentous, but rather opaque or turbid, nebulous or dotted, presenting just such an appearance as marks the earliest stages of fatty degenerations in the muscular fibrils. In such coagula as these, also, one sees, not unfrequently, minute, shining, black-edged particles, which we may know to be drops of oil; while some general alteration in the composition of the fibrine is shown by its not being made transparent with acetic acid. In all such cases as these the fibrine is also very soft, and easily broken: it is devoid of all that toughness and elasticity which is the peculiar characteristic of well-formed fibrine; and by breaking it up, one may see the meaning of what one so often finds in the lowest forms of inflammatory exudation, such as occur in erysipelas and typhus,—namely, films and fragments of molecular and dotted substance, floating in fluid that is made turbid by them, and by abundant

* Lancet, Report of Medico-Chir. Soc., April, 1860.

† Principles of Medicine. Rokitsansky has always held that the fatty and earthy matters of degenerations are residues of the transformations which the higher compounds of the tissues have undergone; part of the products of the transformation being absorbed, and part (at least in many cases) remaining in the place. See, also, the Lectures on Nutrition, p. 40.

* Vol. i. p. 229.

† As in a case in the Museum of St. Bartholomew's, ser. xii. 55.

‡ As in the College Museum, No. 1756 A, and 1757.

minute molecules and granules and particles of oily matter. These represent the disintegration of fibrine that has degenerated after clotting, or has thus solidified in an imperfect coagulation. Of such changes, also, an excellent instance is presented in the softening and disintegration of the clots within the heart, which Mr. Gulliver* has described, and which might be studied for the illustration of the corresponding changes in inflammatory lymph.

We have examples of numerous varieties of this degeneration and disintegration of fibrine formed in inflammation. It is a principal constituent of most of what has been called "aplastic lymph," in inflammation of the serous membranes. Similar fibrine occurs, mingled with mucus, in the severer inflammations of the mucous membranes. And to the same source we may trace most of that molecular and granular matter which is usually mingled with pus formed by the suppuration of inflammatory indurations—with the variously changed corpuscles of "scrofulous matter"—or with the granule-cells, and other corpuscles of pneumonia, and the like inflammations. At least, this disintegration of fibrine is probably a frequent origin of such molecular matter; while the quantity of fatty matter present in pus and the products of pneumonia, and its gradual increase,† while pus is retained in an abscess, confirm the view, that the changes here described are of the nature of fatty degeneration.

When we see how a large mass of inflamed hard substance will become fluid, as it suppurates, and this with scarcely any, if any, increase of bulk, we may believe that another change of which fibrine is capable in degeneration is its liquefaction. In such a swelling as a hard bubo, or a hard chronic abscess, we may be nearly sure there is coagulated fibrine, both from the general circumstances of the inflammation, and because neither corpuscles alone, nor fibrine in the liquid state, would give such hardness. The suppuration, therefore, of such a swelling, if without increase of bulk, can hardly be explained, except on condition of the fibrine, which had coagulated, becoming again liquid. The occasional liquefaction of clots out of the body‡ makes this more probable; but I am not sure that it can be proved by any more direct facts.

I may here refer to a point of some practical importance connected with these

forms of degeneration of lymph, whether affecting fibrine or corpuscles. When the fibrine has withered and become dry, it is probably put out of the capacity of being further developed, and is rendered passive for further harm or good, except by its mechanical effects. But the molecular and fatty degenerations are yet more beneficial, in that they bring the lymph into a state favourable to its absorption, and, therefore, favourable to that which is termed the "resolution" of an inflammation in which lymph has been already formed. I suppose it may be considered as a general truth, that the elements of a tissue cannot be absorbed so long as they retain their healthy state. There is no power of any absorbent vessels that can disintegrate or decompose a healthy portion of the body: for absorption, there must be not only an absorbing power, but also a previous or concurrent change, as it were a consent, in the part to be absorbed; so that it may be reduced (or, rather, may reduce itself) into minutest particles, or may be dissolved. And this change is probably one of degeneration, not death, in the part; for dead matter is rather discharged from the body than absorbed.

Now there are some facts which indicate the probability that the fatty degeneration is that which commonly precedes the natural absorption of many normal parts; or, rather, that, in the change which they undergo before absorption, fatty matter is one of the products, and that the principal evident difference between the atrophy of a part which is manifested by its wasting, and the atrophy which is manifested by fatty degeneration, is, that the fatty matter, which is absorbed in the former case, is retained in the latter. However this may be, it is certain that the disintegration and fatty degeneration of the fibrine-products of inflammation bring them into a state most favourable for absorption; indeed, one may see in fibrine thus changed many things which, in regard to the fitness for absorption, make it parallel with chyle.* Of such absorption of fibrine we may find many instances. In rheumatic iritis we may believe the lymph to be fibrinous; but we see its complete absorption taking place; and the recent observations of Dr. Kirkes on the rarity of adhesions of the

* See also the ingenious contrast of the progress of chyle and the regress of pus drawn by Gerber, in his *Allgem. Anatomie*, p. 48.

One assumes that the absorption of visible particles is possible here, as it is commonly assumed to be in chyle; but the passage of such particles through the membranous walls of blood-vessels is only imaginable. Can it be that they pass into the vessels by being incorporated in the tissue adjacent to them, and then by being gradually shifted into them in the mutations of particles that are effected in nutrition?

† *Medico-Chirurgical Transactions*, vol. xxii.

‡ Gerber, *Allgem. Anatomie*, 48.

§ As in cases by Nasse and De la Harpe, quoted by Henle, in his *Zeitschrift*, B. ii. p. 169. See also Virchow on the same subject, in the *Zeitschrift*, B. iv. Henle refers to this same liquefaction the changes that ensue in emitted semen.

pericardium, in comparison with the frequency of pericarditis,* may be in the same manner explained. In rheumatic pericarditis we may be sure fibrine is effused; and the observed friction-sound has, in at least one case, proved its coagulation; yet in this case, when death occurred four months afterwards, scarce a trace of fibrine was found in the pericardium: it had been absorbed, and the degeneration I have been describing was probably the preparation for its absorption.

3. I am not aware of any direct proof of the calcareous degeneration ensuing in the fibrinous part of an inflammatory exudation; but we have the strongest evidence from analogy for believing that this change may be a frequent one. For there are numerous instances of calcifications of fibrine within the vessels—as, *e.g.* in the ordinary formation of phleboliths from clots of blood, in the branching and irregular pieces of bone-like substance found in obliterated veins, and in the lumps and grains of substance like mortar imbedded in fibrinous deposits in the heart's valves. We can, therefore, hardly doubt that the fibrine, even before development, may take part in formations of earthy matter in inflammatory products; but the calcareous degeneration is much more frequent in purulent fluids, and in the later developments of lymph.

4. Lastly, we have examples of the pigmental degenerations of fibrinous lymph in the various shades of grey and black which often pervade the lymph formed in peritonitis, and which are produced, not by staining or discoloration of the blood by intestinal gases, but, according to Rokitsky, by the incorporation of free pigment-granules.

Such appear to be the degenerations of the fibrinous lymph of inflammation: such at least are the changes in it which we may refer to defects in its power or conditions of nutrition, because they correspond with changes that may be traced in the gradual degenerations of old age. I need hardly say, that it is only by such correspondence that we can interpret them; for when we find them, it is altogether beyond our power to tell, by direct observation, whether, or in what way, the conditions of nutrition were defective.

The corpuscular constituents of lymph, in any of their stages of development, may retrograde, and then present degenerations corresponding, and often concurrent, with those which I have just described.

a. Their withering is well seen in some forms of what is called scrofulous matter,

such as occur in chronic and nearly stationary scrofulous enlargements of lymphatic glands. In the dull ochre-yellow-coloured and half dry material imbedded in such glands, may be found abundant cells, collapsed, shrivelled, wrinkled, glietening, and altogether irregular in size and form. One might suppose them to be the remnants of pus dried-up, or the corpuscles of chronic tuberculous matter, if it were not that among them are some with nuclei shrivelled like themselves, and some elongated and attenuated, which are evidently such as withered after they had been developed into the form of fibro-cells; into which form it is certain that neither pus-cells nor tubercle-cells are ever changed.

These are the best examples of withered lymph-corpuscles; but they may be also found in the pus of chronic abscesses, especially, of course, in that of such abscesses as ensue by suppuration of lymph-deposits like those just referred to. It may be hard sometimes to say whether corpuscles in these cases may not be pus-corpuscles shrivelled up: but, on the whole, I am inclined to believe that the shrivelled corpuscles of the pus of chronic abscesses are usually derived from the lymph, in which, having withered, they had become incapable of further change.

b. The fatty degeneration of lymph-cells is shown in their transition into granule cells.* We owe the first demonstration of this to the excellent observations of Reinhardt,† who has also shown how, by similar degenerations, corresponding forms of granule-cells may be derived from the primary cells of almost all other, both normal and abnormal, structures.

This method of degeneration appears peculiarly apt to occur in the inflammations of certain organs—as, especially, the lungs,‡ brain, and spinal cord; but it may be found occasionally prevalent in the lymph of nearly all other parts, and in the granulations forming the walls of abscesses or of fistule. It may occur alike in the early forms of lymph-cells, and after they have already elongated and attenuated themselves, as for the formation of filaments, and after they have degenerated into pus-cells. The changes of transition are briefly these:—The lymph-cells, which may have at first quite normal characters, such as I have assigned to “pri-

* The exudation-cells of Dr. Hughes Bennett; the inflammatory globules of Gluge.

† Traube's Beiträge, B. ii. 217, *e. s.*

Observations similar to part of those of Reinhardt were made independently by Dr. Andrew Clark (see MEDICAL GAZETTE, vols. xiii. xliii.)

‡ Dr. Gairdner describes also the formation of granule-cells from epithelium-cells in pneumonia (Contributions to the Pathology of the Kidney, p. 20).

mordial cells," present a gradual increase of shining black-edged particles, like minute oil-drops, which accumulate in the cell-cavity, and increase in number, and sometimes in size also, till they nearly fill it. The fatty nature of these particles is proved by their solubility in ether: and their accumulation is attended with a gradual enlargement of the cell, which also usually assumes a more oval form. Moreover, while the fatty matter accumulates, the rest of the contents of the cell becomes very clear, so that all the interspaces between the particles are quite transparent; and, coincidentally with all these changes, the nucleus, if any had been formed, gradually fades and disappears.

I need hardly say, that in these particulars the changes of the lymph-cells, (which may also occur when they have been already developed into the form of fibro-cells,) correspond exactly with those of the fatty degenerations observed in the cells of the liver or kidney, or in the fibres of the heart. There can be hardly a doubt of the nature of this process; and it presents an important parallel with the similar changes described in fibrine. For, we may observe, first, that where this degeneration is apt to occur in lymph, it is least likely to be developed. A proper induration and toughening of the lungs and brain, such as might happen through development of the products of inflammation, is extremely rare; it is scarcely seen, except in the scars by which the damages of diseases are healed. And, besides, this degeneration is a step towards the absorption of the lymph; for commonly we may trace yet later stages of degeneration in these granule-cells. They lose their cell-walls, and become mere masses of granules or fatty particles, held together for a time by some pellucid substance, but at last breaking up, and scattering their components in little clusters, or in separate granules.

Thus, if at no earlier period of their existence, or after no fewer changes, the lymph-corpuscles may pass into a condition as favourable for absorption as is that of the fibrine when similarly degenerate and broken up: and such as this, we may believe, is a part of the process by which is accomplished that "clearing up" of the solidified lung, which is watched with so much interest in pneumonia.

c. I may speak very briefly of the calcareous and the pigmentary degenerations of the lymph-cells. The former appear in cases such as Henle* refers to, in which granule-cells are composed not wholly of fatty matter, but in part also of granules of earthy matter. In this combination they correspond with

the common rule; for the fatty and earthy degenerations are usually coincident: they are combined in the advanced stages of the degenerations of arteries, and may be said to have their normal coincidence in ossification. Of the pigmentary degeneration of lymph-cells there are, I suppose, examples in the black matter effused in peritonitis: but the best examples are in the cells of bronchial mucus, to which I have already referred.

But I pass quickly by these, that I may speak of the degenerations of lymph-cells into pus-cells, or, more generally, of the process of suppuration that is connected with inflammation. The purulent is the most frequent degeneration of lymph, ensuing in nearly all cases in which it is placed in conditions unfavourable to its development—as, in the persistence of inflammation, or in exposure to air, or in general defects of vital force.

Of the conversion of lymph into pus we have numerous evidences; but a few may suffice for the proof.

1. The fluid of such vesicles as those of herpes is, in the first instance, a pure lymph, containing corpuscles which might be taken as types of the lymph- or exudation-corpuscles. If we watch these vesicles, we see their contents not increased,—rather, by evaporation, they are diminished; but the lymph is converted into pus, and pus-cells are now where lymph-cells were. And the changes may ensue very quickly: I think I have known it accomplished in twelve hours at the most.

2. In like manner, when we watch the progress of an abscess, we may find one day a circumscribed, hard, and quite solid mass, and in a few days later the solid mass is fluid, and this with little or no increase of bulk. Now the incipient solidity and hardness are due to lymph; the later fluid is pus, and the change is the conversion of lymph into pus.

3. The relation of lymph- and pus-cells is also shown in this that; they often cannot be distinguished from one another. Even in common suppuration of a granulating wound, the granulation-cells (which cannot be distinguished from lymph-cells) appear to be convertible into pus-cells; superficial cells being detached in pus, while deeper ones are being developed into filaments. But in worse-formed granulations, as in those lining a sinus or fistula, the cells are often by no characters, except by their forming a solid tissue, distinguishable from pus-cells. One may see the same conversion of lymph into pus thus illustrated: an amputation through the thigh was performed when all the parts divided were infiltrated with lymph effused in connec-

* In his Zeitschrift, B. II.

tion with acute traumatic inflammation of the knee-joint. Next day pus flowed freely from the wound. Now, in an amputation through healthy tissues, free suppuration does not appear till after three or four days: the pus here seen must have been formed by the conversion of the lymph previously infiltrated in the divided tissues.

These facts, while they may prove that the pus-cells are commonly the result of degeneration of lymph-cells, may also serve to show that the question whether pus-cells are ever formed in another way, or are ever an original or primary product of inflammation, cannot be positively settled. We cannot always discern a preliminary lymph-stage; but neither can we always distinguish lymph-cells from pus-cells, nor can we see in how very brief a time the transformation may be accomplished.

Assuming, however, that, when it appears as an inflammatory product, the pus-cell is always either an ill-formed or a degenerate lymph-cell, we may believe that, of the various forms which it presents, some depend on the peculiar defectiveness of the lymph; some on the state which the lymph-cell, previously well-formed, had attained before its degeneration began; and others on the further degenerations which may have taken place after the characters of the pus-cell have been acquired.*

I would especially observe, that in specimens of what might be called "good" pus, we may find three principal forms. There are—1st, some corpuscles presenting the peculiar and well-known granulated or wrinkled appearance of pus-cells, but from which water will raise up no cell-wall; 2d, from others, like these at first sight, water will raise a cell-wall, and will show that the former kind consist of only such a substance as forms the contents of these; 3d, in others, even when no water is added, a cell-wall is visible, and within this are granulated contents, with a more or less distinct nucleus imbedded in them. In all these forms, moreover, the addition of acetic acid usually displays a single or a bipartite or tripartite nucleus. Now, it may be that these represent three different stages of the pus-cell, either developing, or, more probably, degenerating; but I think it is much more likely that these forms are the results of the purulent degeneration beginning in lymph-cells at different stages of their development. There is so remarkable a correspondence between these three varieties of pus-corpuscles, and the three chief forms

which I described as observable in the development of the primordial cell of lymph, that one cannot but suspect that the three forms in the pus represent corresponding and similar degenerations from the three forms in the lymph.

When once formed, the pus-cells, if they are retained within the body, have no course but to degenerate further; it is characteristic of their being already degenerate, that they can neither increase nor develop themselves. The various corpuscles found in pus, besides those I have already mentioned, must find their interpretation in these degenerations; for the pus-cells are prone to all the degenerations that I described as occurring in the lymph-cells.

a. They may wither, as in the scabbing of pustular eruptions, or in long-retained and half-dried strumous abscesses.

b. Or, they may be broken up, whether before or after passing into the fatty degeneration, which is one of their most common changes, and in which they are transformed into granule-cells. It is this breaking-up into minute particles which, probably, precedes the final absorption of pus.

c. Or, lastly, both the cells and the fluid part of the pus may alike yield fatty and calcareous matter, and this may either remain diffused in fluid, or may dry into a firm mortar-like substance.

It is to such degenerations as these, in various degrees and combinations, and variously modified by circumstances, that we must ascribe the diverse appearances of the contents of chronic abscesses and of the substances left after their healing. In such abscesses we may find mixtures of pus-cells, granule-cells, and molecular matter, diffused in more or less liquid; or all cells may be broken up, and their debris may be found mingled with minute oily particles, which appear in all such cases to be always increasing; or, with these may be abundant crystals of cholesterine, or such crystals may predominate over all other solid contents. In yet other chronic abscesses (though, still, without our being able to tell why the pus should degenerate in these rather than in the foregoing methods), we find molecules of carbonate and phosphate of lime, mixed with fat-molecules and crystals, which are diffused in an opaque white fluid, and look like the deposit of lime-water, or like white paint; and as these contents dry, in the healing of the abscess, so are formed the mortar-like deposits and the hard concretions, such as are found in the substance of lymphatic glands, or other organs that have been the seats of chronic abscesses.

Time and patience would fail in an attempt to describe all the varieties of mate-

* It may be added that other rudimental cells, besides those of lymph, may be so altered as to resemble exactly the ordinary pus-cells. In many of the supposed cases of pus in the blood, the bodies taken for pus-cells were certainly only altered white blood-corpuscles.

rial that may thus issue from the transformations of pus. What I have enumerated are the principal or typical forms with which I believe nearly all others may be classed.

In conclusion of this part of the subject, a few words must be added respecting the degenerations which may occur after the lymph-products of inflammation are completely organised. All these degenerations, to which I have now so often referred, may be observed in fully-formed adhesions, or in the corresponding organised tissues in the substance of organs.

Of the wasting of adhesions we often see instances in the pericardium, where films of false membrane are attached to one layer of the membrane, while the opposed portion of the other layer is only thickened and opaque. A more remarkable instance, also, is presented in a case by Bichat, in which a man made twelve or fifteen attempts at suicide, at distant periods, by stabbing his abdomen. In the situations of the more recent wounds the intestines adhered to the walls of the abdomen; in those of the older wounds, the older adhesions were reduced to narrow bands, or were divided and hung in threads.

Of fatty degeneration I have seen no good examples in adhesions or similar inflammatory products, but of calcareous degenerations, or of such as present a combination of fatty and earthy matter, museums present abundant specimens. Among these are most of the plates of bone-like substances imbedded in adhesions of the pleura, in thickened and opaque portions of the cardiac pericardium, in the tunica vaginalis, in old hydroceles, in the thickened and nodulated capsule of the spleen, in the similarly altered mitral and aortic valves. So, too, many of the so-called ossifications of muscles and ligaments are examples of calcareous degeneration of fibrous tissue formed in consequence of inflammation of these parts, and imbedded in masses of fibrous-looking bands within their substances. In some of these cases, indeed, there may be an approximation to the characters of true bone; but in nearly all, the earthy matter is deposited in an amorphous form, and seems to take the place of the former substance, as if, according to Rokitsansky, it was a residue of the transformation of the more organised tissue, whose soluble parts have been, after decomposition, absorbed.*

Pigmental degeneration of adhesions may be seen, sometimes, in those of the

pleura, in which black spots appear like the pigment-marks of the lungs and bronchial glands.* Adhesions of the iris, also, may become quite black; I suppose by the formation of pigment like the uvea.

Such appear to be the chief instances of degeneration ensuing in the more or less developed products of inflammation. Doubtless, the account which I have given of them is very incomplete, and in its details sometimes erroneous; yet I venture to think it may be useful to my fellow-workers in pathology, by helping them to keep the right direction in our labours.

Among the signs of the attainment of complete membership in the economy we may enumerate this,—that the organised product of inflammation is liable to the same diseases as the parts among which it is placed; that it reacts like them under irritation; is like them affected by morbid materials conveyed to it in the blood; and like them may be the seat of the growth of new and morbid organisms. No more complete proof of correspondence with the rest of the body could be afforded than this fact presents; for it shows that a morbid material in the blood, minute as is the test which it applies, finds in the product of inflammation the same qualities as in the older tissue to which it has peculiar affinity.

The subject, however, of the particular diseases to which these substances, themselves the products of disease, are liable, has been little studied. As I have already said, lymph, while it is being highly organised, is often the seat of hæmorrhage; its delicate new-formed vessels bursting under some external violence, or some increased pressure, and shedding blood. Such are most of the instances of hæmorrhagic pericarditis, and other hæmorrhages into inflamed serous sacs.

Even more frequently, the lymph, when organised, becomes itself the seat of fresh inflammation. Thus, in the serous membranes, we may find adhesions in the substance or interstices of which recent lymph or pus is deposited; or, in other cases, adhesions, or the thickenings and opacities of parts, become highly vascular and swollen. It is, indeed, very probable that, in many of the instances of the recurring inflammations that we watch in joints, or bones, or other parts, the seat of the disease is, after the first attack, as much in the organised product of the former disease as in the original tissue.

As an example of the inflammation of organised inflammatory products, I

* Numerous specimens of the calcareous degeneration of adhesions were shown from the College Museum, including Nos. 103, 1493, 1494, 1516, 1548, 2367, 3456, &c.

* As in No. 96 in the College Museum.

may present a specimen which has some historic interest.* It is one of those by which attention was first drawn to the connection between acute rheumatism and disease of the heart. It was presented to the College by Sir David Dundas, in 1806, and he sent with it a letter,† in which he says that it exemplifies a disease of the organ "which is not described by any author that I am acquainted with, but which, from the number of cases which have fallen under my observation, is, I apprehend, very frequent in this country. The most remarkable circumstance of this disease is its being always connected with, or subsequent to, an attack of acute rheumatism." In relation to the subject of which I was speaking, the specimen has this point of further interest, that it shows such a deposit of recent lymph among the old adhesions as, we may be sure, was derived from their vessels.

I suppose, also, that to such inflammations of organised inflammatory products we may ascribe many of the occasional aggravations of chronic inflammations in organs—the renewed pains and swellings of ankylosed joints, of syphilitic nodes, and the like,—which are so apt to occur on exposure to cold, or in any other otherwise trivial disturbance of the economy. In such cases we may believe that the former seat of disease is again inflamed, and that with it are involved the organised products of its former inflammations. And in such cases there are, perhaps, none of the effects of inflammation which may not ensue in the newly organised parts: evidently, they may be softened, or thickened and indurated, and made more firmly adherent: or they may be involved in ulceration, or may slough with the older tissues among which they are placed.

Lastly, the products of inflammation may be the seats of the morbid deposits of specific diseases. In their rudimentary state they may incorporate the specific virus of inoculable diseases, such as primary syphilis, variola, and the rest; and when fully organised they may be the seat of cancer and tubercle. But on these subjects I have not time to dwell, although their pathology, especially as illustrated by the tuberculous diseases of serous membranes, is full of interest.

Original Communications.

OBSERVATIONS ON THE CONDITION OF THE BODY AFTER DEATH FROM CHOLERA.

By WM. FREDERICK BARLOW, M.R.C.S.
Resident Medical Officer to the Westminster
Hospital.

(Suggested by a Case communicated to the
Writer by THOS. GREEN, M.D. F.R.C.S.,
Surgeon to the Bristol Infirmary, &c.)

AN extreme apathy has, as might have been anticipated, long since succeeded to the intense excitement which prevailed whilst the cholera was raging; and there are many who may think it an injudicious moment to ask attention to anything respecting it; but I venture to address myself to those who, not behaving as though it were absolutely certain never to return, still contemplate its phenomena, and confess how much many of them need more research.

During October last I read an account in the *Times* of an "extraordinary case" of cholera, which happened at Bristol. It was described as "a supposed case of catalepsy," and subsequently as one of "suspended animation." It was reported to have "exhibited, perhaps, some of the most singular phenomena" on record. It was affirmed, too, that the subject of it had been heard to say, "that if he should die of cholera, he should like to be stabbed in the heart, so that he might be certain not to be buried alive." Rumours of every sort were spread on all sides: the public listened readily, as it always does,—was alarmed needlessly, as it often is.

The death which so many fancied to be simulated was, in truth, real all the while, as real as any death ever was, whether by cholera or other malady. An inquest was held upon the body after decomposition had become evident, and the fact of dissolution could be denied no longer. At this inquest "the utmost interest was manifested, and the jury-room was crowded, as well as the approaches to it." A great check must have been given to the

appetite of the marvelling, by the Coroner observing that "the usual signs of death were well known, and, though some of these signs were wanting, it did not follow that death had not taken place."

The body had very long remained warm, and rigor mortis had been extremely tardy, and the Coroner remarked, on these points, that "the absence of coldness and rigidity frequently occurred, but there could be no doubt that death had taken place."*

Dr. Wallis and Mr. Kelson, two of the medical attendants of the deceased, gave evidence during the inquiry which went to prove how little true cause had existed for the extravagant excitement which the case had occasioned; but at the same time there were circumstances stated by them of considerable medico-legal interest.

Desirous of the fullest particulars, I wrote to Dr. Green, Surgeon to the Bristol Infirmary, who also was consulted respecting the case, and he was so kind as to send me an account, which I have taken the liberty of abridging.

It appears that Mr. B. B.—h went to his counting-house at 9 A.M., Oct. 12, 1849, and returned at 10, feeling ill, with severe pain, vomiting, and frequent watery evacuations. Some medicine and brandy were prescribed him.

At 4 o'clock there was great pain in the abdomen and legs; the voice was feeble; there was no pulse at the wrist; the face was pale and collapsed; the eyes half closed and sunken; the mind undisturbed. No urine was passed; there were vomiting and the characteristic rice-water evacuations; he would "roll in bed" with the intensity of the cramp. The tongue, however, felt warm; so did the skin and extremities.

A scruple of calomel was ordered to be taken, and a draught containing opium and ammonia, acetate of lead with small doses of morphia, external warmth, a mustard poultice to the whole abdomen, &c., were subsequently had recourse to.

When seen by Dr. Wallis, Dr. Green, and Mr. Kelson, at a later period of the day, there was a relief obtained from the vomiting, purging, and some from the cramps, whilst the skin kept warm; but still there was no pulse at the

wrist. Difficulty of breathing, with intense pain through the waist (spasm of the diaphragm?) was noticed.

When visited at 10 o'clock, this pain was relieved; the dyspnoea had ceased; there had been no return of the vomiting and purging; the skin was warm and perspiring; but there was scarcely, if any, pulse at the wrist: and so he continued until about half-past 1 o'clock in the morning (Oct. 13th), when, his bowels pressing for relief, he would get upright (in spite of the nurse, and contrary to what had been strictly enjoined him), passed a watery evacuation, and died in about twenty minutes.

"At 6 A.M., Oct. 13th," says Dr. Green, "I saw the body: the skin was warm; limbs not rigid; features not collapsed. I directed that he should not be buried until I had seen him again.

"At 6 P.M. I found he had been screwed down in his coffin: the lid was removed by my direction, the body taken out, and found still warm, and in the same condition as in the morning. The entire body and extremities were then closely packed in saw-dust

"Oct. 14th.—Had remained during the night in the saw-dust; the warmth still continued; there was no rigidity; a vein in the arm was opened, but no blood came.

"At 12 at noon, tepid salt and water were injected slowly in a vein of the arm; some frothing of the mouth followed; * next powerful galvanic shocks were passed from the back of the neck in the direction of the heart for half an hour: no other means were used.

"The saw-dust was then removed, and the body laid out in the usual way.

"15th.—Heat less.

"16th.—Body cool.

"17th.—Body quite cold; limbs rigid; appearances of decomposition over the abdomen.—To be interred."

An account of the post-mortem examination was given at the inquest by Mr. Kelson: it presented nothing remarkable.

As to the measures which were resorted to with the apparent view of restoring animation, it will naturally be asked why they were not earlier employed? The answer is, that the me-

* The words "absence of coldness and rigidity" are evidently intended to imply only unusually long delay.

* This is commonly enough noticed in dead bodies on their being disturbed or moved.

dical advisers never expected any good from them, and only used them to satisfy the friends of the deceased. They never doubted that the death was real, but were placed in difficulty by the unusual circumstances which surrounded it.

Dr. Green informs me that he considers the patient hastened his death by the effort to raise himself upright. Very likely. Many victims of cholera have suddenly perished in the moment of exertion, and the same may be said of other diseases which severely prostrate. In 1832 I was called to a man who lay in the collapse of cholera: he was cold, livid, dying. On a sudden, and without my being able to prevent him, he rose from his bed, would have fallen on the floor had I not supported him, and died in an instant. I could cite other like instances, were it necessary.

In the history before us there was nothing during life-time, as the late epidemic will fully prove, remarkable in any way; and as to what happened after death, there was nothing which should have set people marvelling to the extent they did, making them most anxious for the daily journals, that they might learn what had transpired in the "Bristol case" since the last report. But there were undoubtedly certain circumstances of no trivial interest to the scientific inquirer, which it may be well to dwell upon shortly, and the rather as a misconception of them may tend to the extension of erroneous views, and, perchance, at some future time, cause like events to be wrongly canvassed.

That a body dead on the 13th of October, and so early as half-past 1 in the morning, should not have been "quite cold" until the 17th, on which day rigor mortis seems to have first shown itself, and signs of putrefaction to have been first seen, is a fact which certainly requires comment. I could wish the task were in abler hands.

Now was there anything in the situation of the body subsequent to death which could account for any of the phenomena observed? Was the corpse covered or not?—exposed to a high or low temperature?—to a tolerably or a quickly moving air? Was ought to explain an uncommon absence, or the absence of a common

There were four points in the which principally attracted attention.

1st. The long retention of wa-

2d. The deferred rigidity.

3d. The delay of putrefaction.

4th. The aspect of the features, of which nothing has been said at present: it was placid, like that of the sleeper.

As to the first matter, it will doubtless have struck the reader that the packing of the body in saw-dust had, in every probability, much to do with the retention of the heat. It would be against reason not to conclude so; and such is the opinion of Dr. Green, Dr. Wallis, and Mr. Kelson; such that of Dr. Alfred Taylor and others to whom I have mentioned the facts of the case. Still, it seems clear that there was something not a little uncommon in the temperature of the body, and that the long-continued heat was far from being altogether owing to the bad non-conductor wherewith it was surrounded: the corpse, as we see by the account, had less heat on the 15th, was called "cool" on the 16th, and not pronounced quite cold until the 17th, though it was removed from the saw-dust about noon on the 14th. Inferring from Dr. Green's narration that the face was left uncovered whilst the rest of the body was completely enveloped in the saw-dust, I made inquiry of that gentleman whether the exposed part did not become more quickly cold than the rest of the body. Dr. Green says, in a note, "I took care that the face should be entirely uncovered. The next morning there was not much, if any, difference between the temperature of the face and other parts; but on the morning of the 15th the face was decidedly colder than the rest of the body." From this we may gather that the saw-dust operated in keeping, or helping to keep, the body warm: indeed, it could not have done otherwise; but the corpse appears to have been very slow in cooling even when there seemed nothing to prevent its doing so. I asked Dr. Green to inform me of the circumstances under which the body lay subsequently to its being removed from the saw-dust, of the temperature of the atmosphere meanwhile, &c., and I learn from him that it was laid on a board, dressed as are usually, and covered with a sheet. The room in which it lay was at night. The following day the window was open in the day. The temperature of the weather at the time was about 50° in the shade. In five days the body was found dead:—

Saturday, Oct. 13th, 45°, wind East.
 *Monday " 15th, 45° " East.
 Tuesday " 16th, 47° " E. S.E.
 Wednesday 17th, 60° " W. S.W.

From hence we may conclude that the body was slow in cooling even when by no means unfavourably situated for losing its warmth quickly, when the temperature was moderately low, the wind being in the east the while, when the window of the room was open at day-time, and the body lightly covered.

No doubt it would have been very instructive to have had some observations made carefully by the thermometer in the case of Mr. B——, setting forth plainly a true comparison between the heat of the body in life and death, and marking to a nicety the slow degrees by which it lingeringly left the body; but it is not surprising that they were not effected, seeing how every moment of the time of most practitioners was occupied during our late dreadful and memorable visitation of cholera, wherever the pestilence thickly raged. And I must be permitted to say, that it would be absurd to put aside all observations on the ground that they might have been exacter and more delicate. As a rule, we know by our touch when bodies are hot and cold; and in taking the temperature of patients under different circumstances, the thermometer is continually verifying what we have ascertained, though not with enough minuteness, by the hand, which, to test a matter of this kind, is confessedly an infinitely ruder instrument. Persons have felt the bodies of these dead by cholera, and given a *concurrent* testimony that they were warmer, greatly warmer, than in life-time, and surely we must admit their evidence notwithstanding no thermometer was used.† I know that some of the profession have been summoned to the dead by reason of their growing warm; they obeyed the call as one of the fancy, but were soon obliged to confess the existence of, to their minds, a strange and novel phenomenon.

In the case before us it is not stated

* Sunday was not mentioned; but the temperature observed at Greenwich was, highest, 46°, wind N.E.; lowest, 37°, wind N. N.E.

† I presume in almost all cases where evidence is given upon inequities and trials, that where the warmth or coldness of the dead is mentioned by the medical witness, he refers to what he ascertained by the touch. The thermometer should certainly be oftener used.

that there was any *rise* of heat; the long duration of it was the striking circumstance. Perhaps the same phenomenon would have been seen in other instances of cholera had they been patiently, enduringly watched. But as far as my own experience goes I have nothing to contribute on this head. As to what usually happens after various deaths, Dr. A. Taylor says—"it is very rare that the heat of the body is preserved for so long a period as twenty hours. In general it becomes cold within ten or twelve."* This observation, however, only applies, and is doubtless intended only to apply, to the external parts of the body. Organs and strictures imbedded deeply hold their warmth long after the surface, exposed perhaps to the cold air all but entirely, has parted with its heat, or with so much of it as to chill the hand of living persons. A little inquiry has told me that the thermometer often exhibits the presence of a degree of heat far higher than that of the surrounding atmosphere when the body strikes cold to the touch, and that it proceeds to lose it very gradually.

In inquiries into the remaining heat of the dead the relative temperature of the different parts should be accurately taken: it is not enough to examine the axilla, and leave the matter there. In a girl, aged 18, a sufferer from morbus Brightii, whereto succeeded diffuse bronchitis, coma, and death, I found, 24 hours after dissolution, the atmosphere being of the temperature of 40°, that the thermometer proved 60° of heat in the axilla, whilst 72° were found in the kidney. In another instance, wherein there was also renal degeneration followed by a rapidly fatal apoplexy, there was a still more considerable difference between the heat of the kidney and the axilla. But let me refer to some remarks, by Dr. Davy, on the temperature of the body after death, in which the comparative amount remaining to various organs was minutely examined. The following is one of the instances which he cites:—

"—, aged 29; died of pulmonary consumption on the 26th January, and was examined eighteen hours after. There was great emaciation; little blood; there were the ordinary lesions

* See his instructive and valuable Lectures on the Signs of Death, published in the MEDICAL GAZETTE. Vol. for 1827 and 1828.

in the lungs, with empyema of left pleura, and ulceration of ileum and cæcum.

	Deg.
In longitudinal sinus (calvaria unusually thin)	55
In lateral ventricle	55
In upper part of spinal canal	55
Under integuments of sole of foot	48
" " dorsum of foot	44
" " thigh, close to artery	52
In purulent fluid of left pleura (48 oz.)	64
In right ventricle, moderately distended with blood, partly liquid, which afterwards coagulated	63
In left ventricle, empty	64
In central substance of right lobe of liver	65

The observations were made in succession, without interruption, in the space of five minutes. The temperature of the room the greater part of the time was 40°.* It appears from this and other observations that not only must the external and internal parts of the body be contrasted, but the latter compared one with the other. *Cæteris paribus*, the most exposed portions most rapidly cool. How could it be otherwise? Make the skin internal and the heart external, and the latter loses its heat the more quickly. The uncovered arm of the dead is soon frigid, the covered preserves its heat. The other day a man was brought into the Westminster Hospital completely dead. He had strangled himself with a small rope which had left the deep mark of its effectual compression. His ordinary dress was on him; the parts enveloped by it were warm, but the hands and other exposed portions of the body were quite cold. In the dying as in the dead we note frequently the effect of external cold, and the partial failure of animal heat is a not uncommon foreshadower of dissolution; the paralytic limb is warm or chilly, as it is laid open to the air or not; and the leg robbed of blood, though temporarily, by Hunter's operation shows the same fact. These are points known to all, but perhaps dwelt upon to the full by few. There is a multitude of occasions wherein the effect of exposure and covering must be well accounted for. *Imparted* must be distinguished from *self-generated* heat. A part will mortify despite the warmth

that is not its own; it can be raised in temperature as dead matter may. There may be life with extreme coldness, death with much warmth. The questions are, what has led to the production of either state—transient or permanent? and how is it influenced in every way?

The temperature of the body after death by disease in general has been hitherto but very insufficiently considered; and the consequence is that we are but ill prepared to treat of the matter as respects cholera. Yet the subject is of too great interest to justify our ignorance, is no doubt intimately connected with the phenomena exhibited by the disease in life-time, and has, probably, far more numerous, various, and useful bearings than we should make bold to guess. But as far as the profession itself is concerned, it is certainly incumbent that it should acquire some knowledge of the question: it should be prepared, at any rate, to be more informed than those who may consult it in legal inquiry.

The most curious matter connected with the subject is not the *maintenance* of temperature, but its *rise*.

The editor of the Cholera Gazette for 1832, remarks, in a note, that the warmth of the body increases long and remarkably after death; to him it was clearly no rarity, and yet I could point to most able writers on the scourge referred to, who devote not a syllable to the matter, and could also mention some of my acquaintances who have had a very unusual experience of the disease, and have never observed the phenomenon.

Cruveilhier, in his famous work on pathology, speaks of the coldness in this disease being less intense in the dead than the living, stating:—"Le froid de la peau est moins intense sur le cadavre que sur le vivant, ce qui tient en grande partie à l'absence de cette sueur visqueuse qui inonde la peau pendant la dernière période du choléra: chez plusieurs sujets, au bout de dix-huit heures, la chaleur du tronc s'était maintenue à peu près comme dans l'asphyxie."

The circumstance of the heat thus augmenting, and being retained thus long, is certainly one which I think could hardly have been anticipated in a disease wherein in life-time there is so general and signal a failure of the animal warmth,—which in fact takes

* See Researches, Physiological and Anatomical, by John Davy, M.D., F.R.S., Vol. i. p. 262.

rank amongst the most prominent and ominous features of this dreadful affliction. Strange, that the body which feels so cold in life, that we all but shrink from the icy chill of its impression, should, after the last pulse has beat, the last breath been taken, impart so much warmth to the toucher, alarm perhaps some anxious relative who, with senses made keen by affection, bends himself solicitously over the body, sure to discover anything unusual, and make the most of it when known.

What means this manifestation and retention of heat? With what is it associated? Is it connected with those singular disturbances of the muscular fibre whereby the face is agitated and the limbs moved? I have in a former essay referred to a case in which the heat rose and the muscles contracted. Dr. Taylor makes mention of another—and more, doubtless, have been seen—in which this elevation of the animal heat and marked signs of muscular irritability were beheld simultaneously; but there is no reason to believe that they appear together as any other than *coincident* events. The motion has often happened without the heat, the heat without the motion.

In the two following examples which occurred last year, under the notice of Mr. Hunt, who communicated them to me, there were no contractions noticed, though the rise of heat was palpable enough.

Ellen Connor, æt. 50, died at 49, Duck Lane (a place full of dirty, crowded, ill-ventilated apologies for dwelling-houses, and in which the late epidemic raged frightfully), of an attack of cholera, after being ill twenty hours; she was extremely cold in life-time, but after death was found much warmer than her son, who, stricken with the same malady, lay beside the corpse of his mother, and died three hours afterwards. Mr. Hunt was told by the relatives of the man, that his body, also, became warmer after life was past.

Jane Welch, æt. 7 years, died of the same disease, after an attack of 12 hours' duration. Mr. Hunt examined the body carefully in life-time, and it everywhere struck him with a "sudden chill." But after the child was dead two hours, he was sent for hastily by the parents, who were wishful to ask him if it were not living, for the body had become warm and the cheeks somewhat red-

dened. Mr. Hunt placed his hands upon the body and felt a "glow of warmth," and was for a moment inclined to hope, but soon convinced himself how irrecoverably the heart and respiratory muscles had ceased to act.

It cannot be questioned that very many instances of rise of temperature altogether escaped observation; first, because so many of the dead were not carefully examined; secondly, because the mode of examination by touch in some of the cases wherein it was employed, could not have measured those *slighter* elevations of the temperature which may be assumed to have occasionally happened. The extreme examples were no doubt detected readily; even the most ignorant could find them out.

Dr. Taylor refers to some instances in which the thermometer was used:—"In many cases of death from cholera in 1832-3, the body which had become moderately cold was observed suddenly to resume its warmth, so that the temperature is stated to have risen some time after death, as high as 87°, although the circulation and respiration had entirely ceased."

As to the cause of the *post-mortem* warmth, Cruveilhier, as we have seen, inclines much to refer it to the withdrawal of the cooling influence attendant upon the evaporation of moisture from the surface which took place in life-time. This view may be sometimes capable of explaining the lessened coldness to *some extent* in marked cases of increased heat, but not nearly to a degree that is satisfactory. Have any observations been made to show that those bodies which were most bedewed with cutaneous exhalation exhibited after death a higher temperament than others which were less moistened by it? But in reference to its refrigerating effect in life-time, we must remember how closely and thickly many of the bodies were carefully covered, so that a free evaporation from the surface, whereby heat could largely and quickly escape, was effectually prevented.

At the time of death by cholera there is an amount of internal heat which must be diffused and become external ere the body be cold throughout; but surely it cannot be successfully contended that enough remains to explain a very palpable rise and a much more than common retention of warmth. As

it is diffused so it is diminished; when it gains the surface it must be of less intensity than it was before. Other circumstances being equal, the warmer the body at the instant of death the longer does it take to cool: some lose their heat in great part before they die; not so others, certain of those, for instance, destroyed of a sudden by disease, accident, or purposed violence. In reference to the case which occurred in Bristol, it must be recollected that the patient was warm when he died, and further, that his dissolution was apparently hurried by a sudden effort: had he lived longer, so as more gradually to perish, it is very doubtful whether the heat of his body would have lingered so long as it did. The quicker the dissolution the more likely is the temperature to be long retained,—the more probable is it, also, that rigidity will be postponed, and decay retarded.

Since the rise of temperature which occasionally happens after death by cholera is found often in the absence of muscular contractions, it would be out of question to gravely refer thereto by way of accounting for the production of the heat. And were the heat never found except in combination with the movements of the muscles, it would still be futile to appeal to them to explain the cause of warmth. There is nothing in the observations of Becquerel and Breschet, who found that the temperature of a muscle increased 2° by violent exercise, which can show reason for any considerable augmentation and duration of heat. Besides, we must have a due care not to apply indiscriminately to the dead what has been discovered to happen in the living, as to change and amount of temperature. For animal heat bears a certain relation to the energy of the circulation, and the blood speeds more swiftly when the muscles play. But mere muscular action when no blood is circulating,—such, for example, as may be brought about by galvanism when life has left,—does not, in every probability, originate any thing like that increase of warmth which would be generated by motion under different circumstances. How cold the cholera-stricken are in life-time, despite those horrid and pertinacious cramps which violently, and sometimes almost universally, pervade the tortured frame!

Has putrefaction any concern in the production of the increased temperature

after fatal cholera? In some intestinal affections it is well known that putrefaction happens early: in cases of obstruction and puerperal fever decomposition has very hastily appeared; but in cholera I never remember to have noticed any unusually rapid signs of decomposition on the surface of the body. Cruveilhier asserts that “the putrefaction of the body is slow in this disease, as in all subjects drained of their blood; but that the putrefaction of the alimentary canal is, on the contrary, very rapid, as in all cases of considerable sanguineous congestion of the digestive organs.” Generally speaking, the obvious putrefaction of the dead is delayed until they have become cold: they are warmer at the moment of dying than at any time subsequently. Did the rise of temperature after death from cholera begin later than it does, keep pace with advancing putrefaction, become most intense where this process was most manifest, there might be better grounds for speaking of decomposition as the cause of the heat than seem to exist at present. Every one knows, who has been much in the dissecting-room, that bodies in the very height of putrefaction will strike the hand with no sensible degree of warmth. The degree of heat where the body sometimes rises after death is a subject likely to puzzle the philosopher, and for the reason, partly, that we are rightly wont to connect augmentation of temperature with increased nervous energy and accelerated circulation. When we lay our hand upon the dead body, and find that it has become warm, we are naturally surprised at a circumstance so very unusual. “The power of generating heat,” says Mr. Hunter, “seems to be a property in an animal while *alive*.”* But heat is, in some mode or other, generated in the dead sometimes, and, as I am persuaded, otherwise than by putrefaction. Chemical changes, of which the chief is the formation of carbonic acid, do, as it seems to me, go on in the body after dissolution, and give rise to that amount of temperature which is occasionally noticed.

* See Experiments and Observations on Animals with respect to the power of producing heat. Hunter's Works, Palmer's Edition, vol. iv. p. 131. Some of the many difficulties wherewith the subject is surrounded are most emphatically set forth, and the contribution abounds in the most invaluable suggestions as to further investigations.

Hitherto we have thought that the body of the dead when once cold invariably remains so, but we must remember how little, how superficially, the condition of corpses as to temperature has been investigated. In this, as in every other matter, the chief cause of ignorance has been deficient inquiry. Dr. Taylor observes, in reference to the state of the temperature of the dead by cholera—"It is scarcely to be imagined that the function of calorification should for an instant continue in the really dead; and yet certain facts connected with malignant cholera would almost seem to establish the possibility of this." But further on he says—"Possibly a sudden vital reaction in the nervous system may have given rise to the effect observed."*

Mr. (now Dr.) Mayo remarks in his *Outlines of Pathology*—"Magendie antithetically observed that Asiatic cholera begins where other diseases end—in death. And certainly many of its features impress us with the idea of some extraneous and peculiar force of prostration which extinguishes life; and—which is, indeed, most wonderful—seems to act upon life by depressing without exhausting the vitality of the organization. This language, I am aware, is too fanciful for sober physiology; but it is suggested by certain remarkable features of the disease yet unadverted to. It is well attested that in many cases of the most formidable type of cholera, when the patient for two or three hours before death has been cold, blue, motionless, the limbs stiffened with cramp,—upon death taking place the limbs and the jaws have begun to move in slow convulsions, the skin has become sensibly warmer, and the blue tinge has gone off, changing to a mottled red,—as if the organization, which had been borne down during the struggle between life and the disease, could temporarily re-exert its forces when the pressure which extinguished life had ceased."

But *what* "forces of the organization" are thus "temporarily re-exerted," and *how*? Is the heat, as to formation, simply similar to that of life-time, in being dependent on the like chemical combinations, though they take place under completely opposite circum-

stances? Supposing carbonic acid to be formed, whence comes the oxygen that combines with the carbon,—how are its elements brought together that they may unite? Does the oxygen exist within, or does it proceed from without, furnished in abundance by the air itself, as a distinguished animal chemist* will be seen to suggest presently? Is the elevation of temperature confined to the *skin*, or is it diffused wherever there are vessels? Is it always accompanied by a change of colour on the surface, by that mottled red which Mr. Mayo mentions, and which I have had occasion to observe myself? How much, how very much, remains to be explored ere we can gain any satisfactory knowledge of this subject! The late epidemic, with its thousands of deaths, has scarcely taught us any thing about it.

Knowing that Dr. Garrod had made much inquiry into the state of the blood in cholera, I requested him to have the goodness to state his view of the most likely way in which he considered the rise of heat after death to be occasioned. As it will be better to lay his own words before the readers, I beg attention to a literal copy of a letter wherewith I have just been obliged by him.

"63, Harley Street, April 1850.

"MY DEAR SIR,—You ask my opinion as to the probable cause of the increase of temperature observed frequently to occur in the bodies of patients who have died of cholera. I think, in the first place, that it is impossible that putrefaction should have any share in the production of the phenomenon, as the time at which it occurs shows; and also the fact that cholera bodies are not at all prone to decomposition. It must, therefore, be some other chemical change, and I conceive that the following must be the explanation;—During the collapsed stage of the disease, the blood, from imperfect circulation, &c., is prevented from being properly oxygenised, and hence a venous blood is circulating in all the vessels of the body, accounting for the cold stage. After death, however, the blood in the superficial capillaries becomes acted upon by the oxygen of the external air, and the formation of carbonic acid, with the production of heat, ensues: this heat

* Vide op. cit.

† Vide p. 328.

* Dr. Garrod.

often for a time much exceeds in amount that which is abstracted by the cooling influence of the surrounding air: after death from most other causes, the blood, having become oxygenated during life, no further heat is evolved, and the ordinary cooling process ensues.

"I am, dear sir,

"Yours faithfully,

"A. B. GARROD.

"W. F. Barlow, Esq."

It is unnecessary to ask the attention of the reader to these observations. That the oxygen of the air does act upon the blood in the capillaries may be inferred from the fact of the livid colour of the body giving way occasionally to a red tint. The same thing has been noted in the asphyxiated, and perhaps in these also some warmth may be generated, after the breathing has ceased, by the aerial oxygen acting on the carbon of the venous blood, where-with the superficial vessels are charged heavily. If the view suggested by Dr. Garrod be a right one, the skin would probably be found in such instances as he refers to (were a thermometer carefully and properly employed) warmer than the parts beneath.*

It would be interesting to know whether the augmentation of heat be invariably accompanied by change of colour, and whether those bodies become most elevated in temperature which are most livid at the time of death. It would be of moment to know, also, the relative effects of exposing some parts to the air, and of keeping others, as far as possible, excluded from it. Changes of the blood in the capillary vessels *may* partly explain long *maintenance* of heat where the body is exposed to the air, and not in cholera only, but other cases. As the chemical combinations, on which the heat may be supposed dependent, are of quick or gradual completion, so will the warmth of surface hasten away or linger. We are supposing a case in which a high temperature, so far as mere *chemical* changes go, is produced *immediately* by the same causes in the living. Though oxygen be no more supplied from within by ever fresh and flowing currents of arterial blood, it may be obtained from without; but now it acts upon stirless,

not moving blood, producing changes which, quite compatible with the most absolute death, serve no perceivable purpose. As the clot of blood drawn from the vessels reddens when exposed to the atmosphere, so does the still blood in them change colour when the surface of the body lies uncovered after death, for that which intervenes between it and the air suffices not to hinder the influence of the latter. The question is, not as to the fact of influence, but the extent and results of it.

The cause of the coldness of the body in cholera during life-time, is more readily explicable than the rise of temperature after death. The *immediate* cause of animal heat, whatever be the indirect influence of the nervous system,—which is not the less remarkable and obvious because indirect,—is the formation of carbonic acid in the general capillaries, and certain other chemical changes. There is nothing to show that nervous influence of *any* kind can produce heat independently of changes of the blood; but, as the experiments of Sir Benjamin Brodie, the effects of shock, the results of many affections of the body in which the nervous system is more or less concerned, and the physiological relations of that system with the respiration and circulation abundantly prove, we have to deal with no matter of simple chemical changes, but of changes varying with, and varied by, the complex and manifold alterations of condition which life, as a whole, is prone to undergo. All this must be granted.

There is no doubt that many affections of the nervous system may produce coldness indirectly. They act upon the heart and the respiratory movements so as to diminish the sources of warmth; but not to these must we look for the true explanation of the frigidity of cholera, which is certainly more rationally explained by reference to that condition of the blood which forbids the due occurrence of those changes without which the body must decline in temperature. The chief reason of the coldness of cholera would seem to be the non-formation of carbonic acid in the general capillaries. If this be the case, should there not be a great deficiency in the amount exhaled during the cold stage of this disease?*

* It had occurred to Dr. Basham and myself some time ago, that a comparison of the heat of the external and deep-seated parts might tend to some important conclusions.

* I am indebted to Dr. Snow for an interesting case, in which he administered oxygen. In this instance the quantity of carbonic acid exhaled was proved to be very scanty.

I believe it would have been discovered, had sufficiently exact experiments been made, that the intensity of the disease would have been nearly proportioned to the degree of diminution of the proper quantity of exhaled carbonic acid; and that an increased amount of its exhalation would have been found to denote recovery, even as it is foreshadowed by the restored secretion of bile and urine. —I mean, of course, recovery from collapse; for I forget not the coma, overwhelmed by which so many have perished, after exciting false hopes.

There seems to me, as there has seemed to others, some analogy (though I would not push it violently) between an animal with the pneumogastric nerves divided, and a patient dying of cholera. M. Provençal and Sir Benjamin Brodie found that a section of the nerves in question reduced the exhalation of carbonic acid. There is certainly less of it exhaled in cholera, far less than there ought to be.

The respiration becomes embarrassed after division of the pneumogastric; so it does in cholera. And I believe not only that it is purely *voluntary* in the former case, or nearly so, but that very often, in extreme cases of the disease in question, it is performed almost entirely by the will. In the former instance, impressions on the periphery of this nerve are useless, because its trunk is disabled from conveying them; in the latter, I believe that the periphery cannot be properly stimulated, in consequence of the condition of the blood in the putmonary circulation; and that the *reflex* movement of respiration fails from this cause.* Further, less oxygen is inhaled, and animal heat fails in both cases.

So far we may indulge comparison; but manifold differences separate the two conditions. In the first, the blood is affected because of the impaired respiration; in the latter, the respiration suffers and labours because of the damaged blood. Then there are the diarrhoea, the vomiting, the cramps of cholera, distressing with all the sudden and violent operation of some deadly, agonising poison. There is that strange state of blood which explains everything but its own condition,—explains the coldness, the pulselessness, the

lividity, the death,—explains also the too common and palpable failure of remedies; for how can they act when they are not absorbed,—how influence when they do not circulate? The blood's altered consistency alone would seem to explain much. When Mr. Hunter gave the reasons of the blood being fluid, he so hinted at what would happen if loss of fluidity should occur, as to draw a picture which fails not to remind us of some main symptoms of cholera:—"Without being fluid, it could not be propelled through flexible tubes, and distributed to all parts of the body; it could not be divided into portions, as the vessels branch off; it could not pass through the smaller vessels, nor admit of the various separation of its parts which are to produce the increase and repairs of the whole body; neither could it be adapted for furnishing the various secretions; nor could it be brought back to the heart."

Asking pardon for this digression, I would revert to my subject. It must not be supposed that extraordinary states of temperature after death are *peculiar* to cholera. Dr. Davy has observed some facts from which it might be surmised that the thermometer would, in certain parts of the body, demonstrate in some cases much higher degrees of post-mortem temperature than we have now any idea of. His remarks were made at the hospitals in Valetta. A man died of supposed acute rheumatism: there were found large collections of matter in the neighbourhood of the shoulder and hip-joints. The body was examined three hours and a half after death, when the temperature of the room was 86°. It was warm externally, but the deep-seated parts gave to the hand a burning sensation. The thorax and abdomen had been exposed to the air about ten minutes, when "a thermometer placed under the left ventricle of the heart rose to 118°; and under the liver, in contact with the lobulus spigelii, to 112°." What was there in this case which could explain so remarkably high a temperature? In another instance, wherein a man died suddenly, and was examined five and a half hours after death, in a room of the temperature of 86°, the thermometer placed under the left ventricle of the heart rose to 108°; placed under the liver, to 107°. Whence this great heat? In both these cases it will be seen that

* It is needless to say that I adopt Dr. Marshall Hall's view of the office of the pneumogastric as an excitor of respiration.

the greatest warmth was declared by the thermometer being placed in contact with the heart; but Dr. Davy makes statements of other examinations in which there was a difference (in one case of 8°) in favour of the liver. As to the two cases which revealed so extreme a temperature, it must be well remarked that the early period at which they were examined after death would seem to set aside the notion that it was attributable to putrefaction, which, Dr. Davy says, "had not taken place in these bodies,"—"had hardly obscurely commenced." It is not known whether there was a rise of temperature, or only a maintenance of that which, before death, was very high. It would have been most interesting to have known the exact heat of the skin at the time of dissolution.*

It would seem that the condition of the circulation of a part at the time of death may have much to do with its heat afterwards. M. Bouchut, in a very recent work on the signs of death, speaks of the full or empty state of the stomach in reference to the process of cooling, and cites a case placed on record by M. Ollivier d'Angers, in which the abdomen of a man, who died during digestion, was found hotter than other portions of the body. But the observation, like so many others in reference to the heat of the dead, is too vague. What was the difference in favour of the abdomen, and what was the warmest portion of this region?†

Dr. Dowler has detailed, in his "Experimental Researches," some instances of a singularly high post-mortem temperature. The following will show the temperature observed in some cases, and the sex and age of the subjects of observation:—

Sex.	Age.	Temperature.
M.	27	100
—	30	102
F.	26	103½
M.	24	107
—	25	107 to 106
—	29	107½ to 103
—	24	108
—	22	106 to 106
—	26	109 to 102
—	50	109 to 102
—	25	111 to 102

* See Dr. Davy's remarks on these cases, in the first volume of his *Researches*.

† *Traité des Signes de la Mort*. Par E. Bouchut, Ouvrage couronné par l'Institut de France. Paris, 1849. See p. 191.

The temperature was taken soon after death; but the time varied, as the reader may see by turning to the account. Sometimes an hour, or two hours, or more, elapsed before the thermometer was used. The decline of heat was frequently noticed up to a certain point. In many of the instances muscular contractility was readily made manifest by mechanical irritation of the muscles. The comparative temperature of life and death does not appear to have been fully and accurately estimated; but the subject is alluded to, and it is stated that the body of a Philadelphian, "which before death had been remarkably cold, had a temperature after death as high as 109°." The thermometer was, in one case, applied to the chest; in another, to the axilla; but, for the most part, we are left to guess with what spot it was placed in contact. It would, however, seem that the skin was always tested, for nothing is said any where of the temperature of the internal parts. But of what diseases did the subjects of the observations die? The great majority appear to have perished of yellow fever.

The great heat observed in the dead by Dr. Dowler reminds one of the high temperature observed in birds in life-time. The following is Tiedemann's table representing the latter; and I introduce it that the reader may at once compare it with the imperfect one I have constructed with Dr. Dowler's examples:—

	Degrees.
Great titmouse	111-25
Swallow	111-25
Starling, different species	111-25 to 107
Anna, different species	111 to 106
Common hen	109-94 to 102-99
Falcon, different species	109-74 to 104-5
Pigeon	109-58 to 106-7
Raven	109-28 to 105-99
Pullen	107-49
Common cock	103-78 to 102-99
White game	102
Gull	100

A very high temperature has been demonstrated in the human body during life. Even the highest ascribed to birds by Tiedemann, or the highest shown to exist in man, when dead, by Dr. Dowler, has been exceeded by the living frame. Let me allude to a remarkable case or two. The temperature of 106° has been noticed in scarletina by Dr. Dunglison; that of 110-75°

in tetanus, by Dr. Prevost, of Geneva, who communicated the fact to Dr. W. F. Edwards.* M. Riouy is said to have remarked the temperature of 112° in typhoid fever; but, a still higher heat, if observed in the living body,† would, I think, be less calculated to surprise us than the amount of warmth which has been already shown to have happened in the dead. In life-time, the balance between the processes whereby the frame is cooled and heated may be altered in various ways. Much may happen to favour these chemical changes, whereupon animal heat more immediately depends, whilst, simultaneously, the secretion of the skin may be so checked, that the surface shall operate most imperfectly as a diminisher and regulator of the warmth of the body. All parts of the subject need well tracing out, though there be writings,—and I may refer to the Memoir of M. Roger on the Temperature of Infants and Young Children,—in which the pathology of animal heat has been handled with no little ability and care. The subject, in reference to the nervous system, is of singular interest. Facts have come to light in reference to injuries of the spinal cord which compel even the attention of the incurious. M. Chossat found by experiment that division of the superior portion of this organ was the cause of a remarkable elevation of heat. Sir Benjamin Brodie noticed the temperature of 111° , both during life and directly after death, in a case of forcible separation of the fifth and sixth cervical vertebrae, giving rise to paralysis;‡ Dr. Gull lately informed me of an example of unusually high temperature succeeding to, and, no doubt, caused by, injury of the spine. Different parts of the body should, of course, be carefully tested by the thermometer in cases of this kind. Only lately I saw a man with his lower extremities entirely, his upper partially, paralysed by a large effusion of blood external to the

dura mater of the cord: it was consequent upon fracture of two of the cervical vertebrae. At a time when the temperature of the inner surface of the lip was 97° , and that of the axilla was the same, the thermometer rose to 100° on my placing its bulb between two of the fingers or toes. Probably the state of the skin as to perspiration differing in the unparalysed and paralysed parts, may explain some cases of disparity of heat. As is known well enough, there is no *uniformity* as to the matter of temperature in cases of affection of the superior portion of the cord. Cruveilhier has given a most interesting example of spontaneous displacement of the atlas, which gave rise to compression of the cord and hemiplegia.* Coldness of the skin, and the feel of shivering, were prominent amongst the symptoms. Cruveilhier says that the *constancy* of the coldness afforded him always fresh admiration, and even goes so far as to declare that it was so manifest and remarkable during the course of the malady as to lend support to the opinions of those physiologists who consider the spinal marrow as the main source of animal heat.

Of animal heat we have yet much to learn. Viewing it, to speak generally, as proportionate, *ceteris paribus*, to the fulness, freedom, and swiftness of the circulation, and the corresponding energy of the respiratory process, we are but ill prepared to find the high, the extremely high amount of it which has been noted in the dead. In *what* cases the heat absolutely rises after death, and in *what* also it rises *most*, remains to be ascertained. How can we talk of what we have not examined? It has been shown, at any rate, that the rise in question is not peculiar to cholera: and it is certainly required that the more important facts which touch upon this subject should be more generally and completely canvassed, for they have most interesting relations to the signs of death, and may at some future time give birth to medico-legal inquiries, the difficulties whereof, increased alike by rumour and credulity, will alone be solved, if solved at all, by the indispensable, and but too frequently undervalued evidence of medical witnesses.

[To be continued.]

* See On the Influence of Physical Agents on Life. By W. F. Edwards, M.D., F.R.S. Translated by Dr. Hodgkin and Dr. Fisher. See p. 257.

† It has been stated by Dr. Granville that the heat of the uterus has, during labour, risen so high as 120° .

‡ "I have made experiments similar to those of M. Chossat, and have met with similar results. I have also seen several cases in which an accidental injury of the spinal cord has produced the same effect."—See Sir Benjamin Brodie's Observations on Injuries of the Spinal Cord, Medico-Chirurgical Transactions, vol. xii.

BRIEF NOTES
OF
THE EPIDEMIC CHOLERA IN
BALLINASLOE,

IN APRIL, MAY, JUNE, JULY, AUGUST,
1849.

By EDMUND SHARKEY, A.B., M.B., T.C.D.

As Ballinasloe has obtained a world-wide notoriety by the high coloured descriptions of "S. G. O." in the *Times* newspaper, I have thought that a plain unvarnished account of the epidemic which raged here might not prove unacceptable to you. The mortality, though undoubtedly great, was not excessive, the circumstances being considered. The number of cases and deaths which fell to my share were as follows:—

Cholera cases, 624, of which 223 were males.

Do. deaths, 334, of which 126 were males.

The total number of cases of dysentery was 493, of which 197 died.

The total number of cases of dysentery and cholera which occurred in subjects under the age of 15, was 510, of which 218 were deaths.

I must, however, observe, that from the great rapidity with which the disease spread, and the consequent confusion, the accuracy of the above numbers is not to be *absolutely* relied on. It is, however, as accurate as I could make it from the materials I possessed, and is not, in my opinion, very far from truth.

An epidemic dysentery and diarrhoea having prevailed almost universally for several previous months, and proved particularly fatal among emaciated adults and children in the workhouses, giving latterly an average of from 100 to 120 deaths per week; and the keen north and east winds, with frost and snow at intervals, having given place to soft weather, with wind from westerly points, the disease broke out in Boyd's brewery (auxiliary workhouse) on the 23d of April. It spread so rapidly that, on the 28th, when I took charge, there were 85 cases in that establishment, almost all in the third stage. The weather continued warm and sunny, with westerly wind, and the disease increased with fearful rapidity. It was like a spark fallen among tinder. The miserable

remnants of famine and dysentery were carried off in numbers at last too great for a prompt supply of coffins and graves. In one of the auxiliary houses assigned to old and infirm men, there was scarcely such an occurrence as a recovery, however slight might appear the commencement of the attack, and though the subject of it might appear to have some little stamina (for they were not *all* old, many of them were young men, whom the workhouse diet had somewhat restored from the state of starvation in which they had entered), their stamina were only apparent. And I may here remark, in passing, that famine appeared to do its work with more appalling effect among the men than among the women. Nor was I the only visitant of their cabins who observed that for *one* emaciated woman there were met *ten* famine-stricken men; and where the wife kept up an average "embonpoint," the man was frequently a walking spectre. This, I believe, arose partly from the fact of the men continuing to attempt earning a day's wages on little or no food, and partly, I feel convinced, from the poor creatures forbearing to satisfy the cravings of nature in their own persons, for the benefit of their wives and children,—exhibiting in many instances a degree of heroism which I did not expect to see in any race of people, and which I verily believe is, to the same extent, unparalleled in any other country under the sun. It is, indeed, a *sad*, if not a "proud" pre-eminence, attained, alas! by the long continued practice of privation, at the expense of pristine vigour and manhood. There was at last scarcely to be seen an able-bodied labourer; and when such were required for the railway works (undertaken earlier than was expedient, for the purpose of employing the poor people), they were found incapable in very many instances of giving a fair day's work, and were consequently rejected. Thus did their extreme poverty present a barrier to their escaping from it. How true—"Haud facile emergunt quorum virtutibus obstat res angustæ domi," not only in poetry, but in the homely concerns of the working man.

With the exception of the absence of a sense of blowing in the ears, observed in former epidemics to usher in the attack, the symptoms presented no important difference from those observed

by me in former epidemics in 1832, 1833, and 1837. I have been confirmed (if confirmation were necessary) in the opinion, that the first step in the chain which leads from health into this particular disease resides in the nervous system. I was myself on the verge of it in 1837, and again in the late epidemic; and I had no difficulty in recognizing the peculiar, indescribable sensations, referable to the spinal marrow, which in both cases were experienced. In neither instance was there either vomiting or diarrhoea, but a feeling of motion in the spine, as if something were traversing it in the direction of the epigastrium, which required a strong mental effort and perfect quietude of body in the horizontal posture to prevent vomiting. No such feeling was experienced by me in any indisposition at any time before or since; but it was felt more or less, at intervals, during the prevalence of the epidemic.

The treatment which I adopted in the last was in principle and in detail nearly identical with that used by me in 1837, and which I have published in the *London Medico-Chirurgical Review* of Jan. 1839, to which I beg to refer: it was briefly as follows:—

When the disease was ushered in by diarrhoea, I at once commenced the acetate of lead and opium, which, though often useful, was not found possessed of the almost specific virtues which have been attributed to it.

When the first stage of the disease came on I administered a tea-spoonful of the following tincture in warm punch: if given in the very onset (as in my own case), the effect was frequently to produce a glow of heat, followed by profuse perspiration, which continued for some hours, and left the patient free from complaint, but weak. It was as follows:—*R. Camphoræ, 3j.; Tinct. Opii, ʒss.; Tinct. Cardam. C. ʒiss.; Ol. Ment. Pip. gtt. xij. M. Sum. cochl. min. j. pro dosi, si opus repetend.* The usual appliances for restoring temperature, viz. dry heat and dry friction to the surface and extremities, were adopted, and the most vigilant precautions used against any effort on the patient's part to leave the horizontal position. Small doses of calomel (gr. ss. to gr. j.), with capaicum, were given at short intervals, with ammoniacal mixtures and punch (cold water being also freely allowed). Opium was sparingly

administered, except per anum, in which mode it never seemed to do any harm, and frequently much good, an enema of Plumbi Acet. ʒij.—3j.; Tinct. Op. ʒj. in ʒiv. (or less) of Mucilag. Amyli, sometimes effectually checking the diarrhoea.

The secondary fever was found, of course, most formidable, especially in children; and from its rapidity, when once set in, I was driven to the practice, as soon as reaction began, of uniformly applying, as a prophylactic, blisters to the calves of the legs, not waiting till the dangerous symptoms should manifest themselves.

From the class of persons I had to treat, I was seldom called on to abstract blood; indeed, it was not to be thought of in the great majority of cases, for the usual signs of arterial action or sanguineous determination were absent. The subjects of this fever were principally children; and none but an eye-witness could conceive the phase of withered childhood which the Irish famine of 1849 produced. To see the little sufferers lying in their beds, you never could say (except by the smaller proportions) that you were not gazing on a specimen of most emaciated old age. The wrinkled skin, sometimes overgrown with tufts of long lank down; the rigid muscles running as well-defined cords, and appearing to loop up the angles of the mouth, throwing the sunken cheek into a deeper hollow, and further degrading the expression below humanity into that of a superannuated baboon; while the little face had so fallen away, that the naturally well-proportioned forehead seemed by the contrast expanded into hydrocephalic dimensions; and both viewed in front giving the appearance of an inverted wedge. Long had I been in the habit of seeing various forms of Irish poverty, but never before starvation—never before an infant population labouring under a universal marasmus. It was, indeed, a sight to harrow the heart. I often wondered how steeled I had become, that I could look on such things without weeping.

The head was the organ generally attacked. Only one case, within my knowledge, terminated in peritonitis. The form of the head affection in this secondary fever is peculiar. There is frequently an absence of the ordinary accompaniments of this complication in

other fevers, viz. heat of head, strong arterial action, violent delirium, &c.; its only indices being a heavy expression of the eyes, somnolency, muttering, but with the power of recalling thoughts and speaking rationally while attention was kept up, the patient afterwards relapsing into the same dreamy state; and this condition, accompanied by an uncontrollable vomiting, every thing being rejected, and yellow or green matter, in apparently inexhaustible quantity, ejected from the stomach. This form I have chiefly observed in strong adult subjects.

As to the contagious, or rather infectious, nature of the complaint, my views continue unchanged since I wrote a short paper in the *Dublin Journal of Medical Science*, Sept. 1889, to which I beg to refer. Two of our nurses died, and two others had the disease each three times. These latter were two of the strongest women in the house, and were perfectly free from fear. Another had it twice. One of the medical gentlemen sent down to our assistance had likewise a slight attack. That infection is not the only source of the disease I need hardly say. There is a peculiar atmospheric influence at work, which, acting especially on the nervous centres, predisposes it to the disease; and upon anything occurring to upset the equilibrium of the system, hurries it on into it. A melancholy case in illustration of this occurred in this town. Dr. James Colahan, being convalescent from some febrile attack, during the prevalence of cholera here, wished to go for change of air two or three miles into the country; and while driving on his way thither, through the misconduct of a drunken coachman, the horses ran away. Dr. Colahan jumped out, and fell. The shock brought on instant vomiting, the malignant form of the disease set in, and he sank. He was a young man of high promise, and was universally liked and deeply lamented.

In making these few observations I feel that I have not said anything new; but as it is the third epidemic which I have had an opportunity of witnessing, and as the confirmation of past experience is not to be despised in medicine, I submit them to my brethren with a feeling akin to that of the tempest-tossed mariner, who, when the storm is past, looks back with gratitude upon the waste of waters where many a stout ship has

been engulfed, while his own frail bark has been graciously spared; indulging the humble hope that this brief summary may not be destitute of interest.

Bellinasloe, April 9, 1890.

CASE OF HOMICIDAL WOUND IN THE ABDOMEN.

By C. A. GORDON, Esq., M.D.
Surgeon, 57th Regiment.

CORPORAL JOHN GRACE, 57th Regiment, aged 22 years, of strong and healthy constitution, was at half-past 5 A.M., on 2d November, 1849, brought to hospital, suffering from inability to void his urine, and complaining of severe pain in the perineum. There was a small and apparently trifling wound, into which a probe was introduced to the depth of an inch, in a downward direction in the parietes of the abdomen, about midway between the pubis and umbilicus, and a little to the left of the mesial line; and, on being questioned, he stated that about eleven o'clock the previous night, while in a scuffle with a civilian, he received a severe kick in the perineum, and was at the same time conscious of sustaining some injury in the abdomen; but afterwards walked upwards of a quarter of an English mile to his barracks, where, having to undress in the dark, he did not observe the blood that issued from the wound, nor did he suffer in any way until about half-past four o'clock, when he awoke labouring under the symptoms for which he was sent to hospital.

On admission, two ineffectual attempts were made to introduce the catheter. Venesection was then employed; fomentations applied to the abdomen, and a draught, consisting of half a grain of tartar emetic, twenty-five minims of tincture of opium, and an ounce of camphor mixture, administered at intervals of half an hour. After the third dose urine flowed freely.

The report of the case in the medical register states that, at a quarter past four P.M., he has not voided urine, and now suffers a good deal of diffused pain around the wound. The surface is cool, and he is free from pyrexia.

Bowels have not been moved since he came to hospital.

At half-past nine p.m. of the 2d, the pain in the abdomen continuing, and the pulse being 120, and small, venesection was performed. He had half a grain of tartar emetic, and half a grain of opium, every two hours; and the bowels being confined, an enema of gruel was administered, but did not operate.

On the morning of the 3d, he was reported not to have slept during the previous night; has voided urine three times; bowels have not been moved; tenderness of abdomen less; surface moist; pulse still rapid and small; tongue coated with grey ash-coloured fur. An ounce of castor oil was now administered in enema, and fomentations ordered to be continued to the abdomen.

The noon report states, that within the last hour the pain in the abdomen has increased in severity. The countenance is assuming a more anxious expression. He now states, that early during the night he was seized with shivering, and that he again experienced a sensation of coldness immediately before the present accession of pain. The enema has not yet operated. Pulse small.

At eleven p.m.—He continues to suffer much from pain in the abdomen. The bowels have not been moved, further than that the enema has been voided. The expression of the countenance is very anxious, and the features are assuming a sunken appearance. He is reported to have been incoherent during the evening, and now talks somewhat wildly. Surface cool; tongue loaded as above described; pulse 140, and small.

The treatment at this stage consisted in the administration of a pill, containing one grain of calomel, a quarter of a grain of tartar emetic, and half a grain of opium, every second hour since noon, fomentations being kept constantly applied to the abdomen; and now, while these remedies were continued, at regular intervals, an ounce of castor oil, with two drops of croton oil, and twenty drops of tincture of opium, were administered.

At seven a.m. of the 4th, it is stated that within the last half hour a decided change to the worse has taken place; he is deadly pale. The pulse at the

wrists is almost imperceptible, and he is quite incoherent. The medicine operated very freely during the night, and he now voids fæces and urine in bed. While this report was being written he sank and died.

Post-mortem appearances thirty-two hours after death.—Abdomen: a wound of half an inch in length and a quarter of an inch in breadth was observed in the abdomen, situated three inches below the umbilicus, and half an inch to the left of the mesial line. This wound extended through the left rectus and deep abdominal fascia, in which it formed an aperture of an inch and a half in length, and half an inch in breadth. It was then traced through the large omentum, and entered one of the convolutions of the ileum, in which it formed a small aperture of about a quarter of an inch in extent, the edges of which were surrounded with inflammation, with some lymph adhering.

The peritoneum presented marks of most extensive inflammation along its entire extent, and a large quantity of purulent effusion existed throughout the whole of the abdominal cavity, and occupied spaces between the folds of the small intestines, the external surface of which was also extensively inflamed.

REMARKS.—This case is looked upon as being of considerable importance, showing, as it does, the very serious nature of an injury that, under certain circumstances, it is possible to inflict upon a person, without his almost being aware of it; for here we have a soldier receiving his death-wound by the hand of a murderer, and yet afterwards walking a considerable distance; going to bed as usual, and for a period of upwards of five hours not being at all aware of the nature of the wound; to which his attention was soon then accidentally drawn.

We also from it see, that in some cases of wounds of the abdomen, that excessive sinking and anxiety which are supposed invariably to attend such injuries, do not actually occur.

Dublin, June 1, 1850.

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 21st inst.:—W. T. S. J. Hardy—W. S. Brown—J. T. Hillier—A. Fraser—S. E. Grammer—H. W. Jones—A. E. Brett—K. P. Watt—R. Elaper—C.

MEDICAL GAZETTE.

FRIDAY, JULY 5, 1850.

WE are now entering on that period of the year when, in 1849, the cholera began to declare its intractable character and fatal progress. The time is yet early to institute a comparison; nevertheless, we are disposed to draw a favourable augury from the present state of the weekly returns of mortality. Experience has shown that there is a close relation between the fatality of diarrhoea and the epidemic outbreak of cholera,—the former proving more or less the precursor of the latter. The deaths from these two causes during the months of June 1849 and 1850, are given in the subjoined table:—

1849.			1850.		
Week ending	Diarr.	Chol.	Week ending	Diarr.	Chol.
June 2	16	9	June 1	15	0
" 9	20	22	" 8	19	2
" 16	36	42	" 15	17	1
" 23	17	49	" 22	18	0
" 30	30	124	" 29	33	2

For some weeks past the deaths from diarrhoea have been slowly on the increase; but this is not unusual at this season of the year. We do not find that the increase of the deaths from cholera in 1850 has hitherto kept pace with those from diarrhoea, as in June 1849; and, so far, there is reason to hope we may escape another outbreak during the ensuing summer.

A close examination of the Registrar-General's returns shews that, since the disappearance of the cholera in the latter part of last year, the health of the metropolis has undergone a considerable improvement. An able statistical paper on this subject has been recently published by Dr. John Webster;* and

from this we learn, that while some diseases have exhibited a diminished rate of mortality, others have shown an increased rate, and others again have maintained a uniform progress. The last quarter of 1849, and the first quarter of 1850, compared with the corresponding quarters of 1848-9, shewed a difference in the total deaths of 4064, or about 13·5 per cent. During the first three months of 1850, the deaths were fewer by 2219 than during the same period of 1849; i. e. even before the cholera had manifested itself in the form of a malignant epidemic.

The principal diseases which have undergone a diminished rate of mortality are scarlatina, typhus, small-pox, cholera, influenza, and hooping-cough. Of the cholera, Dr. Webster remarks:—

"But during the first quarter of the current year the contrast has been marked, and highly satisfactory; not more than eight persons having died of cholera since the 1st of last January, instead of 516 during the first three months of 1849. The fact now stated is highly important, and may, I hope, be taken as an indication that cholera will not prove so epidemic and pestilential during next summer and autumn as it was last year."

The mortality from a few diseases has increased. This has been especially observed with respect to measles, and in a less degree with diarrhoea and dysentery.

The great and sudden diminution in the rate of mortality, which took place in the last quarter of 1849, is worthy of remark. Thus, if we compare July, August, and September, with October, November, and December, we find according to Dr. Webster that—

"In the former period the total deaths from all diseases were 27,109, but in the latter they decreased to 12,877, being a diminution of more than half, or 54 per cent. Cholera and diarrhoea continued to prevail throughout October and November of last year, though in a rapidly decreasing ratio, so that 976 individuals

* Dr. Webster's Remarks on the Health of London during the Six Months terminating March 30th, 1850.

died of these diseases during the entire quarter; nevertheless, this period, and the first three months of the current year, have proved more healthy than the corresponding period for several previous years."

What are the influences which have contributed to produce this favourable result even up to the present date? Dr. Webster refers them to—

"1. The improved physical condition of the population. 2. The abundance of good and cheap provisions. 3. The less variable, and hence more salubrious, condition of the atmosphere. 4. The increased attention recently given to sanitary measures. 5. The greater care paid by individuals to their own health, in consequence of the alarm experienced during the previous pestilence. And, 6. The removal, by the recent epidemic, of a large number of the debilitated, dissipated, and diseased portion of the population, so that there remained less *pabulum morbi* as compared with former years; while the survivors were also better able to resist the inroads of disease."

We must demur to 3, for since the commencement of March until the present time we have had great and sudden changes in the temperature of the atmosphere:—a difference of from 15° to 20° has been observed in as many hours. As to 4, Dr. Webster admits that more has been said than done:—

"Although much has been recently said respecting sanitary measures, and a few judicious improvements have been commenced, very little advance in the right direction has as yet been made. As I have previously adverted to this subject, and shewn its importance, it is unnecessary for me to repeat my arguments; but I would now again assert as strenuously as formerly, that all nuisances, whether public or private, must be abated. Vested rights, and individual interests, must yield to the health of communities. On this point, *salus reipublicæ est suprema lex*; and, as on such a question there can be no mistake, there ought assuredly to be no compromise."

It has been long an admitted fact, that the deaths in the year following an

epidemic, undergo a great diminution, owing to the removal of the infirm and unhealthy. The cholera epidemic of 1849 is, in this respect, like others recorded by medical writers.

"Similar results followed the disappearance of influenza, which prevailed so severely during the winter of 1847-48. In the quarter ending June 30, 1848, the number of deaths was 3,510 fewer than in the preceding three months. Again, after the cessation of scarlatina, which was unusually prevalent and fatal during the winter of 1848-49, the aggregate mortality decreased; the deaths from all causes registered in the quarter ending June 30, 1849, being 2,422 fewer than those in the three months ending 31st March. Hence, it may be generally predicted, with some confidence, that whenever any epidemic malady prevails, and removes numbers of the population, the subsequent season or year will probably be more healthy, and fewer deaths will occur, than under other circumstances. This arises much from the removal by the previous epidemic, of the subjects most liable to disease; but there may be also other evident causes in operation, although it is often impossible to point out, and still less to define precisely, the association of every influence, however consistent the results may seem with general experience."

For the first time for many years the deaths in the summer months of 1849 exceeded the births; nevertheless, according to the statistical paper before us, the hiatus made by the cholera has been already more than filled up, and we are now increasing in numbers as if no such malignant disorder had been so recently prevalent among us.

"The remarkable excess of births over deaths, which has taken place in London during the last two quarters, is worthy of notice; particularly as history informs us, that increased fecundity is the ordinary sequence of a pestilence. In the first three months of the above period, 4819 more persons were born than died in London; and during the second quarter, the excess was 5,428, thus making a total of 10,237 more births than deaths in six months! And if to that number we add the 4,067

fewer deaths registered during that period, as compared with the corresponding six months of 1848-49, the vacuum made by the cholera will be found already fully filled up; the excess of deaths during July, August, and September 1849, as compared with the same months of 1848, amounting to 13,606, having been replaced by 14,304 persons—10,237 more births, and 4,067 fewer deaths. In fact, excluding immigrants from the provinces, who may be set off against emigrants to the colonies or elsewhere, there are 698 more human beings now resident in London than after the devastating disease of last autumn. This fact is highly consolatory, and tends to shew the compensating power of the laws of nature, at the same time that it indicates the power and care of our beneficent Creator."

Dr. Webster has rendered good service to medical statistics by the publication of this interesting document. We trust that he will be induced to continue his plan of giving to the profession a biennial summary of the health of the metropolis; and that other medical men of equal experience will be induced to follow his example. The method which he has pursued is both scientific and practical, and any one desirous of a model of statistical research, will find it in Dr. Webster's pamphlet.

While on Sanitary Statistics we must not overlook the fact, that in at least one provincial town, a monthly report of the mortality and public health is regularly published. The town which has set this creditable example is Oxford; and the public and profession are indebted to Dr. Greenhill and Mr. Allen for this periodical record of the progress of disease and mortality. The plan pursued resembles that of the Registrar-General, with the useful difference, that instead of three there are six subdivisions of deaths according to ages. Some explanatory notes are also introduced with respect to individual cases.

The publication of such Reports in all the great towns and cities of the empire would be attended with the best results to medical science; and we do not think that members of the medical profession could be more usefully employed than in collecting and publishing facts of this kind. The funds required for this purpose should be provided by local subscription among the inhabitants; or, where this resource fails, the aid of Government should be extended to the support of a plan without which sanitary legislation can make but little progress.

We have great pleasure in announcing to our readers that a Society for the investigation of Epidemic diseases, to be called the *EPIDEMIOLOGICAL SOCIETY*, is now in course of formation. It has been long felt that the subject of the origin and diffusion of Epidemic disease had not received that practical investigation at the hands of medical men which a question so materially affecting the health of nations demanded. The recent visitation of cholera has given a new stimulus to this inquiry; and we think that all practitioners who have had experience in this and other epidemic diseases should at once associate themselves with the new Society.

"Nur wenig Honig giebt die einzelne Biene, aber zusammengetragen schmeichelt er dem Gaumen von Tausenden."

The Society is still in want of support: it is slowly but steadily adding to its numbers. The list of vice-presidents has been filled up; and several gentlemen, likely to promote very effectually the important objects of the Society, have accepted the invitation of the President, Dr. Babington, to become members of the Council. It is expected that in a very short time the Society will be in a position to commence active operations.

Reviews.

On the Operation for Strangulated Hernia. By HENRY HANCOCK, F.R.C.S.E., Surgeon, and Lecturer on Surgery, Charing Cross Hospital, &c. &c. 8vo. pp. 94. London: Churchill. 1880.

THE object of Mr. Hancock's work is the investigation of the merits of the operation for relieving strangulated hernia by the division of the stricture without opening the sac. To this end the author first examines the validity of the objections to the usual operation; he next inquires into the statistics adduced in favour of not opening the sac; and in the last place submits some very judicious observations on the general treatment of these cases.

In reference to the first point, we may observe that an affirmative answer to the following questions will put our readers in possession of Mr. Hancock's opinion on the subject. For the facts and reasonings with which he ably supports this opinion we must refer our readers to the work itself: to quote portions thereof, would be, by mutilation, to impair the practical value of the author's remarks.

"In the first place, then, are these objections valid or tenable? Have not the authors in question, in their anxiety to support their own peculiar views, overlooked the real cause of failure, and gasped at the shadow whilst they neglected the substance? Have they not, by heedlessly exaggerating the danger of the usual method, and erroneously attributing to the operation the failures which, in reality, resulted from causes entirely independent of such operation, created unnecessary alarm and anxiety as to its probable termination; and thus tended to perpetuate that system of delay, which we have all so much reason to deplore, as leading to 'unsuccessful efforts,' pressure, and bruising the intestines, and postponing the operation until it is merely regarded as a forlorn hope?

Mr. Hancock's examination of the statistics which have lately been adduced in favour of dividing the stricture without opening the sac, shows them to be on the contrary, conclusive against this mode of operating.

In discussing the subject of treatment, the author expresses a strong opinion, which he supports by reference

to the best authorities, that the too long employment of the taxis has been a copious source of fatal consequences. Mr. Hancock demonstrates also the injurious effects of the employment of purgatives, and supports his statements by quoting cases recorded by Mr. Cock, in the Guy's Hospital Reports, in which the advantage of a free exhibition of opium after the operation, and the abstinence from purgatives, are well shown. Under the head of treatment, Mr. Hancock speaks of the beneficial effects of chloroform, which he says he has found to supersede the use of the warm bath, bleeding, opiates, &c. &c., in the speedy reduction of the hernia in many cases, while the patient is spared the dangers resulting from delay and unnecessary handling, where the operation after all has been found necessary, and in the performance of which the author has found chloroform a very valuable aid.

Mr. Hancock appends a few cases and tables which illustrate and confirm his views. We strongly commend the "Deductions," with which the author closes his work, as indeed the whole work itself, to the earnest study of all surgeons.

A Manual of Elementary Chemistry, Theoretical and Practical. By GEORGE FOWNES, F.R.S., &c. 3d Edition. 8vo. pp. 605. London: Churchill. 1880.

WE take blame to ourselves that we have not sooner announced the appearance of a third edition of this useful manual. This edition has been brought out under the superintendence of Dr. Bence Jones; and it is proper to observe that the *Animal Chemistry*, left unaltered by Mr. Fownes, has received from the hands of the editor those corrections and alterations which the advances made in this branch of science had rendered necessary. The work has deservedly found a large circulation among students; and this edition will no doubt have as favourable a reception as those which have preceded it. Its convenient size and portability are strong recommendations, especially when other well-known treatises on chemistry are acquiring a magnitude and reaching a price which cannot fail to frighten a beginner.

Proceedings of Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, June 25, 1850.

DR. ADDISON, PRESIDENT.

Two Cases of Idiots with Absence of the Thyroid Body and Symmetrical Swellings of Fat Tissue at the sides of the Neck. By T. B. CURLING, F.R.S., Surgeon of the London Hospital.

Case I.—In July 1849, Dr. Little invited the author to see a case of *cretinism* at the Idiot Asylum, Highgate, and to examine some swellings at the sides of the neck, the nature of which was doubtful, but which had been suspected to be enlargement of either of the lobes of the thyroid body, or of the lymphatic glands. The inmate was a female child, 10 years of age. She measured two feet six inches in height. The head was heavy-looking, the forehead flat, and the fontanelles inclosed. The countenance had a marked and very unpleasant idiotic expression. The mouth was large, and the tongue thick and protuberant. At the outer sides of the neck, external to the sterno-cleido muscles, there were two tolerably symmetrical swellings, which had a soft, doughy, inelastic feel. Similar swellings, but smaller and less defined, were observed in front of the axillæ. No enlargement existed in front of the neck. The girl had no power of speech, but was able to recognise her parents. She had a severe attack of erysipelas, which was followed by a considerable abscess in the thigh. A second attack, accompanied with glossitis and stomatitis, caused her death fifteen months after her admission into the Asylum. On examination of the body by Mr. Callaway, the swellings in the neck were found to be composed of fat, and to occupy the posterior triangle of either side of the neck, dipping downwards behind the clavicles and filling the axillæ. They were not enveloped in capsule, but consisted of fat of a loose lobular structure.

Case II.—In November 1849, a female infant, *et.* six months, was sent to Mr. Curling for examination, on account of some anomalous swellings in the neck. She had a marked idiotic expression—a large face, with a small head and very receding forehead. The tongue was large and protuberant. On the sides of the neck, lying obliquely across, there were two soft symmetrical swellings, of an oval shape. The

author was struck with the strong resemblance which this case presented, both in respect to the tumors and the general aspect, to the idiot at Highgate. The infant died convulsed December 7th. On dissection, nothing abnormal was observed in the brain, except a remarkably small development of the anterior lobes of the cerebrum. A very careful examination was made of the neck, but no thyroid, nor trace of this gland, could be discovered. The swellings in the neck were found to consist of fat tissue, without any investing envelope, and loosely connected to the surrounding parts.

The author remarks that he is not acquainted with any case on record in which a deficiency of the thyroid gland has been observed in the human body. He considers it highly probable that the abnormal deposits of fat in the neck were dependent on the absence of those changes which result from the actions of the thyroid, or on some imperfection in the assimilating processes consequent on the want of this gland. In conclusion, the author states that in the foregoing cases we have examples of a defective brain, or of *cretinism*, combined with an entire absence of the thyroid, which may be regarded as tending to confirm the more modern opinion, that the coincidence of these two affections is accidental, or that they have no direct relation.

A Case of Hemiplegia, in which Loss of Speech was a prominent symptom. By ROBERT DUNN, M.R.C.S.

The subject of the communication died in a state of coma on the 18th of April last, in the 66th year of her age. It was her third apoplectic seizure. She was of a mixed temperament, the sanguineous and nervous, and of active habits. Her first attack occurred on the 6th of October, 1844, at 4 o'clock in the morning, up to which time she had enjoyed good health. The author, on being called, found her in a state of coma, with stertorous breathing, head hot, face flushed and turgid, mouth drawn down to one side, pulse full and labouring. She was bled and purged freely. In a few hours she became conscious, but was found to be hemiplegic on the right side. Her recovery was quick; she regained the free and full use of the arm and leg, and in a few months her general health appeared to be completely re-established. One peculiarity remained, which arrested the attention of the author, and led him to suspect the existence of some structural lesion of the encephalon,—the habit of using one word for another, and of not applying the proper and appropriate names to the things signified.

Her second attack took place on the 17th

May, 1847. She was found by her daughter on the morning of that day, lying in a state of insensibility on her back, upon the floor of her bed-room. The author was struck with the contrast between the symptoms of this and those of the former seizure. There was the same deep coma, but no stertor; the face was pale, and bedewed with a cold clammy moisture; the extremities were cold, and the pulse was feeble, weak, and fluttering. An opposite treatment was indicated and followed. Ammonia and Hoffman's anodyne were given freely. She was again found to be hemiplegic on the right side. Active reflex movements were excited by tickling the foot, but none could be induced in the upper extremity. She slowly but gradually improved, and ultimately got remarkably well. But she was paralysed and speechless for the remainder of her life. All the special senses were intact; the motions of the tongue were free, and there was no difficulty in deglutition. She was perfectly sensible, and took an interest in passing events. But she could not say *yes* or *no*, and never got beyond the utterance of the monosyllable *dat! dat!* The conscious failure of the effort found expression in a hopeless shake of the head, and often in a gush of tears.

Her last and fatal attack took place on the 14th April, when in the act of being undressed for bed. She was found by the author in a state of extreme collapse and comatose, with loud stertor, and with the left side as helpless as the right, completely paralysed. The teeth were so firmly fixed that nothing could be got into the mouth, and she died on the fourth day of the attack.

Post-mortem examination.—At the post-mortem inspection, the upper two-thirds of the anterior lobe of the left hemisphere was found in a state of disorganization—a pulpy mass; the middle and posterior lobes were healthy. The corpus callosum was destroyed, except at its anterior and inferior reflexion, and so also was the upper half of the corpus striatum on the left side. The optic thalamus was likewise shrunken to less than half its natural size, its upper surface being greatly wasted. The anterior commissure and fornix were gone, but the corpora geniculata were sound.

On the right side the hemisphere was healthy, but when its lateral ventricle was laid open a small and recent apoplectic clot was seen upon the upper and anterior surface of the corpus striatum; the whole of the upper portion of the corpus was in a state of ramollissement, and indications of white softening were seen also on the outer surface of the thalamus. The cerebellum and basis of the brain were healthy.

The author considers the case to present some points of interest in reference to the localization of the faculty of speech. He observes, a great mass of evidence has been collected in support of the opinion of Gall, that the seat of the faculty of speech is in the anterior lobes of the brain. He refers to the memoirs of M. Belhomme and M. Bouillan, read before the "Académie Nationale de Médecine de Paris" in 1848, in support of Gall's opinion, and then cites two opposing cases from Andral's "Clinique Médicale, Maladies de l'Encephale," in which the disease was in the corpus striatum. In considering this subject, he says, it is never to be forgotten that perfect speech—that is, the power of giving utterance to our thoughts in suitable and appropriate language—depends upon the due relation between the centres of volition and of intellectual action; and that, thus considered, the apparently conflicting evidence which has been adduced as to the seat of the faculty of speech, admits, in his opinion, of a satisfactory explication. The thought is framed and moulded for expression in the centre of intellectual action, but the due agency of volitional power, and consequently the integrity of its seat of action, is needed to give it utterance. And while it is universally admitted that the cerebra are the great centres of intellectual action, he believes with Gall, and of which the present case affords corroborative proof, that the anterior lobes are the seat of the faculty of speech; and he asks, Is it not equally true that the corpora striata are the great centres of volition, and therefore does it not necessarily follow that loss of speech may alike result from diseases of the anterior lobes, or of such portions of the corpora striata as are in direct relation with them? He concludes by saying, in the case narrated it is manifestly obvious that with the disorganization of the left anterior lobe its functional power was entirely abolished, and that although the right hemisphere was healthy, and there is every reason to believe, from the history of the case, that it maintained and exercised its function as a centre of intellectual action, still the volitional power was wanting to give utterance to the passing thought, for the corpus striatum was not in its integrity.

On a Case of so-called Chylous Urine.

By HENRY BENGE JONES, M.D. F.R.S.,
Physician to St. George's Hospital.

G—, harness-maker, *æt.* 32, born in Trinidad, came to Scotland when eight years old, and had been in London for twelve years. In the winter of 1848-9 he observed that his urine was at times thick and white. This becoming more continuous, with increasing weakness, he

up work on the 26th of May, 1849. Dr. Prent, among other things, gave him cod-liver oil, and he was sent to Margate for hot sea-baths. On the 19th of October he came to me, complaining of severe pain in the loins, and he passed milky water in my room. The minute microscopical details of the appearance of this urine, which contained fat, albumen, fibrin, blood-globules, and alkaline salts of the blood, are given at length. The urine, each time it was passed, was brought daily to me. The chemical details, with an analysis of the blood, will be published in the next volume of the *Philosophical Transactions*.

Previous to trying any medicines, careful observations were made on the effect of different diets on the appearance of the fatty matter in the urine.

The first series of observations was 71, from Nov. 6 to Nov. 16, when diet was chiefly animal food.

The second series of observations was 91, from Nov. 16 to Nov. 30, when it was chiefly vegetable food.

The third series of observations was 17, from Nov. 30 to Dec. 2, when it was chiefly animal food.

Hence total—

	Very chylous.	Chylous.	Slightly chylous.	Not chylous.
Animal food, 88 observations	3	37	40	8
Vegetable food, 91 ditto	2	20	49	29

Whether the diet was animal or vegetable, the urine was most fatty after dinner; and least fatty, or not at all so, before breakfast. It was more frequently chylous after animal than after vegetable food; and it was oftener free from chyle before break-

fast, when the diet was vegetable, than when it consisted more of animal food.

The effect of pressure by means of a belt was then tried the diet being chiefly vegetable.

	Very chylous.	Chylous.	Slightly chylous.	Not chylous.
4th series, 27 observations, from } Dec. 7th to 11th	2	7	6	12
5th series, 42 observations, from } Dec. 12th to 18th	5	11	12	14
6th series, 53 observations, from } Dec. 18th to 26th	1	16	17	19

From this it appears that, during the days when the belt was tight, the urine was less chylous than on the days when the belt was loose. The difference was not very

great; but the patient stated that the pressure relieved the pain in the back very much. Matico was then tried:—

	Very chylous.	Chylous.	Slightly chylous.	Not chylous.
7th series, 211 observations, from } Dec. 26th to Jan. 26th	7	27	69	108
In much stronger doses— 8th series, 89 observations, from } Jan. 29th to Feb. 11th	1	10	28	60

By comparing these results with the observations when no medicine was taken, the improvement is very evident.

Gallic acid was then tried,—a drachm in the course of the day.

9th series, from Feb. 13, after breakfast, to 16th, 26 observations: after the 14th no fatty matter was observed in the urine.

From Feb. 16th to 20th, 19 observations: no fat or albumen present.

From Feb. 20th to March 4th, 75 observations: no chylous appearance.

From March 4th to 24th (he was at

work), 93 observations: no chylous appearance.

From March 24th to April 6th, 72 observations: no chylous appearance; the gallic acid was stopped.

From April 6th to June 14th, 350 observations: the urine on each occasion was free from chyle or albumen.

The results from the 6th of November to the 14th of June are best shown by supposing 1000 observations in each series had been made:—

	Urine chylous in different degrees.	Free from chyle.
1st. On animal food	968 times.	32 times.
2d. On vegetable food	910	90
3d. With pressure, belt loose	667	238
4th. With pressure, belt tight	638	362
5th. On matico	474	526
6th. On gallic acid	17	983
7th. After gallic acid.	0	1000

The gallic acid was taken for 53 days. On the third day the albumen and fat disappeared from the urine; and for 69 days after the medicine was left off the disease did not reappear, and the patient has resumed his work for 102 days.

A second case is related in which the urine was once observed to be chylous in St. George's Hospital in 1840. Three months afterwards this patient died at Plymouth, and, on post-mortem examination, no disease of the kidney was perceived.

Observations on prolonged Expiratory Murmur as a Sign of Incipient Phthisis. By THEOPHILUS THOMESON, M.D. F.R.S., Physician to the Hospital for Consumption and Diseases of the Chest..

The author, after referring to the opinions of various auscultators, particularly Laennec, Jackson, Fournet, and Cowan, proceeds to state that, in the ordinary healthy condition, the expiratory murmur is very slight, and very little more distinct in one part of the chest than in another; and that in some individuals it is naturally inaudible, excepting perhaps during hurried breathing. In the natural condition he considers the duration of the expiratory sound equal to about a fourth of that of the inspiratory; the inspiratory and expiratory movements being about equal in duration, and three-fourths of the latter being performed in silence. In determining how much of altered rhythm may depend on extension of the expiratory murmur, and how much on diminution of the inspiratory, the author adopts Dr. Sibson's plan of counting the number of strokes which can be given in beating time with the finger during the presence of each murmur. The natural elasticity of the lungs is essential to soft and uniform expiration. Wherever there is considerable consolidation from tubercular or pneumonic deposit, bronchial expiration may be induced; and when the walls of the pulmonary cells are only slightly thickened, and the neighbouring structure is becoming occupied with the glairy, greyish deposit characteristic of early phthisis, the diminished contractility of the cells, interrupted passage of air, and increased power of conducting sound, may be sufficient to render the expiratory murmur more durable, coarse, and audible. A diversity of opinion, however, exists regarding the value of this change of murmur as a sign of incipient phthisis; and the author, with a view to determine its significance, gives in this paper the results of an analysis of 308 cases selected from those out-patients of the Hospital for Consumption in whom he noted prolonged expiratory

murmur as the most prominent symptom. In 20 there was either bronchitis, or emphysema. In the remaining 288 the symptom under consideration was observed almost invariably near the summit of the lungs. In 108 on the right, in 56 on the left, in about 124 on both sides; in this respect contrasting with wavy inspiration, the frequency of which the writer has found to preponderate greatly on the left side (Monthly Journal of Medicine, June 1846). With a few exceptions, referable chiefly to bronchitis or congestion, he has not recorded any instances in which prolonged expiratory murmur, when once established, ever ceased to be obvious, unless superseded by signs of more advanced disease. After describing the usual course of the symptoms, the author mentions that the most frequent special accompaniment was hæmoptysis, which occurred in 91 cases out of the 288; that is, in more than 31 per cent. Assuming that, of the hospital patients taken generally, about 43 per cent. have hæmoptysis before softening takes place, he calls attention to the fact that, whilst on the one hand the coexistence of hæmoptysis in patients with prolonged expiration is sufficiently frequent to strengthen the supposition that there is a connection between this altered murmur and phthisis,—on the other hand the frequency of hæmoptysis in these patients is so much below its average in consumptive cases generally, as to point towards two important conclusions, namely—

1st. That prolonged expiratory murmur takes precedence of other signs.

2dly. That hæmoptysis more frequently follows than precedes the deposition of tubercle.

The writer proceeds to prove, from the facts recorded, the fallacy of the opinion that prolonged expiratory murmur may exist on the right side irrespective of disease; but as this delicate indication may, in a majority of instances, be first detected in that situation, he recommends the careful examination of the upper part of the chest, especially on the right side, with reference to this sound, whenever hereditary phthisis is probable,—a measure which has sometimes led him to detect disease not previously suspected. He concludes with the expression of his opinion, that in the absence of certain sources of fallacy, such as bronchitis and emphysema, this disturbed rhythm of the murmur is the most early and significant sign of phthisis; and that, especially under favourable circumstances, and with appropriate treatment from the first detection of this symptom, the duration of the disease will be found considerably to exceed the period commonly assumed.

Account of a Case in which an Abscess formed in the Vesiculæ Seminales, and proved fatal by Perforation of the Bladder and Extravasation of Pus into the Abdominal Cavity. By MITCHELL HENRY, Assistant Surgeon to, and Lecturer on Morbid Anatomy at, the Middlesex Hospital.

The patient in question, a sailor, 20 years old, was under the care of Dr. Crawford in the Middlesex Hospital. He was admitted on the 19th December, 1849, with symptoms simulating those of hip-joint disease, and extreme pain in the loin and of the left side. His urine was very thick and scanty, and caused burning pain in its passage along the urethra. There was much febrile disturbance, with a quick small pulse, constipated bowels, and a loaded tongue. Leeches to the groin, with calomel, opium, and colchicum internally, alleviated his symptoms for the time; but they afterwards returned with increased severity.

The day after his admission the urine was observed to be loaded with pus, which the patient stated he had noticed at intervals for three weeks before. He denied that he had ever suffered from gonorrhœa, or any form of syphilis, and said he had never experienced difficulty in passing his urine. On the 22nd his febrile symptoms ran so high, that ʒviij . of buffed and cupped blood were drawn from the arm, with some relief. In the evening of the same day blood passed with the urine in considerable quantities, and continued to do so until the 26th, in spite of gallic acid and other medicines which were given to check it. On the 29th violent purging came on, and continued until the next day: it was preceded by pain in the abdomen, but there was no rigor. Medicines and leeches relieved the pain in some measure, and stopped the purging; but on the 3d of January the abdominal tenderness returned, and about 12 o'clock he died in much agony, retaining consciousness to the last.

Post-mortem examination by Mr. Henry, 12 hours after death.—The body was blanched and emaciated, the abdomen tympanitic. There was nothing abnormal discerned in the cavities of the head or thorax.

On cutting open the abdomen it was found to be filled with a great quantity of cream-coloured fluid pus, evidently from an abscess, and not the produce of peritonitis. The peritoneum covering the liver and intestines was inflamed, but not in an extreme degree. The abdominal organs, including the kidneys, were healthy and natural in appearance, except that they were pale. The bladder, which contained some purulent fluid, and was perforated

by an ulcer as large as a sixpence, was removed, together with the penis, testicles, ureters, and kidneys, for further examination.

The source of the pus was so far extremely obscure: the spine, pelvis, hip-joint, particularly the left one, where there had been so much pain, were carefully examined, without throwing any light upon its origin; and it was not for some time that the case was cleared up at all. Finally, however, the remains of a large abscess was discovered in the situation of the left vesiculæ seminalis, which was nearly destroyed by suppuration. The abscess had perforated the bladder by a small rounded hole, and discharged its contents into that viscus; and as at the same time the peritoneum reflected from the side of the bladder had been perforated too, the pus had found its way into the abdominal cavity, and set up the fatal peritonitis. What had excited the inflammation in the vesicula which had preceded the formation of the abscess, is not clear, but the perforation of the bladder must have taken place long anterior to death. The time when the peritoneum became involved cannot however have been far distant from the attack of hæmorrhage by the urethra, which was shortly followed by the abdominal inflammation.

The interest of the case lies principally in this—that the vesiculæ seminales, though not exempt from disease, are very rarely affected with active inflammation, giving rise to symptoms recognizable during life: but there is no reason why the more chronic inflammation, described by Lallemand as extending to them from the ejaculating ducts in severe forms of spermatorrhœa, may not occasionally become more acute, and result in abscess. Such may be the explanation of obscure cases of inter-pelvic abscess, the seat of which is uncertain. In like manner, abscess of the vesicula seminalis may be confounded with abscess of the prostate gland: and lastly, the excessive pain at the neck of the bladder, which now and then follows gonorrhœa, accompanied with shivering and discharge of pus with the urine, may result from an abscess of the vesicula seminalis, which is not of itself, of course, a mortal disease, unless it chance to discharge its contents into the abdominal cavity.

To the case is appended one by Mr. Cock, of Guy's Hospital, where abscess of the vesicula seminalis was diagnosed during life, and punctured through the rectum, with immediate relief. As the patient fortunately got well, the accuracy of the diagnosis could not be tested; but the symptoms were very like those detailed in the case above, especially of the existence of pain in and around the hip-joint.

After the papers had been read, as it still wanted a few minutes to 10 o'clock, the President invited Mr. Solly to favour the Society with any observations he might wish to make on the interesting and practically important case which he had communicated.

Mr. SOLLY observed, his object in bringing the case before the Society was rather to elicit the remarks and opinions of others on the treatment of such cases, than to offer any observations of his own. It was certainly a deeply interesting case,—one involving grave responsibility, which was keenly felt by the surgeon; and therefore it was that free discussion, and the open avowal of the opinions of men of experience, was what he courted and desired. After a most careful review and consideration of the whole case, his own mind rested on the conviction, that the treatment could not have been varied with any chance of different result.

Mr. Solly much regretted there could be no discussion upon Mr. Dunn's valuable paper. From what he could gather from the reading of it, in the first seizure, it appeared the *structure* of the brain was implicated, and the faculty of speech affected, and that this lesion laid the foundation for the subsequent serious affection and loss of speech.

Mr. DUNN said, the peculiarity to which Mr. Solly had alluded, of using one word for another, and of not applying appropriate and proper names to the things signified, was noticed from the time of the first attack. He considered the case to have an important bearing upon the *localisation of the faculty of speech*. One main object of his paper was to show how opposing evidence on this point admitted of a satisfactory explication. The case itself afforded corroborative proof of the opinion of Gale, that the faculty of speech was located in the anterior lobes of the brain. But as the power of perfect speech depended upon the *due relation between the centres of intellectual action and volition*, he maintained that loss of speech would alike result whether the disease was situated in the anterior lobes or in such parts of the corpora striata as are in direct relation with them.

The thought was framed and moulded for expression in the seat of intellectual action,—the anterior lobes; but the *due agency of volitional power*, and the integrity of the corpora striata, as its seat of action, were needed to give it utterance.

The President then congratulated the fellows on the prosperous condition of the Society, &c. &c. and the meeting broke up.

ACADEMY OF MEDICINE, PARIS.

June 18, 1880.

Disinfecting Liquids.

M. HUGUIER read an official report on a disinfecting liquid prepared by MM. Raphanel and Ledoyen, and which had been submitted for the report of the Academy by the Minister of Agriculture and Commerce.

The reporters stated that this liquid, which consisted of a solution of nitrate of lead, appeared to possess disinfecting properties in a high degree; that it is more especially useful where sulphuretted hydrogen is evolved by decomposition; and that it is also effectual for the prevention of putrefaction.

In the discussion which followed on this report, it seemed to be the opinion of the Academy that the report was founded on insufficient data; it was therefore returned to the commission for a more extended series of comparative experiments. MM. Robert and Caventou were added to this commission.

Synovial Cysts of the Wrist.

M. GOSSELIN read a memoir on this subject, of which the following is a summary:—The author made two divisions of those growths—the hydropic, and ganglionic cysts. The first are most frequently found on the sheaths of the flexor tendons of the wrist-joint; they are those that were named "hydatids of the wrist" by Dupuytren, and "crepitant tumors" by M. Velpeau. M. Gosselin states that two distinct bursæ exist on the flexor tendons of the wrist, instead of one, as usually mentioned by anatomists; that some variety, however, is met with in the position of these. This anatomical fact is applied by M. Gosselin to the explanation of the more frequent occurrence of these tumors on the inner side of the joint. The second, or ganglionic cysts, are met with on the dorsal aspect of the wrist, and, according to M. Gosselin, originate in certain normal appendices to the synovial membranes of the joint, which may be regarded as synovial crypts or follicles. The author found a pathogenic analogy between these tumors, mucous cysts, and sebaceous wens.

BIOLOGICAL SOCIETY OF PARIS.

PRESIDENT, M. RAYER.

Monthly Summary, March 1880.

Influence of the Nervus Vagus on the Heart's Action.

M. BROWN-SEQUARD related experiments

from which he deduced conclusions the reverse of those which attributed to the *nervus vagus* a direct influence on the action of the heart. He stated that, having destroyed the ganglia of this nerve, and the *medulla oblongata*, in the frog, the pulsations had remained unaffected for twenty or thirty days. M. Brown-Sequard exhibited two frogs in which these ganglia had been destroyed fourteen days previously, and in which the pulsations of the heart were regular and energetic.

The same physiologist also exhibited several animals in which the reflex and other phenomena of animal life were persistent, notwithstanding the whole or greater portions of the spinal cord had been destroyed.

The Anatomical Characters of the Membrana Decidua.

M. CAZEAU presented an ovum of seven or eight weeks old, expelled entire with its deciduous membranes, by which it was completely enclosed. On minute examination this membrane was found to present two surfaces,—one uterine, the other in relation with the chorion, and between these a cavity; thus supporting the theory of the formation of the *decidua* which regards it as a complete sac, formed by the double layers of the membrane, surrounding the ovum as entirely as the shell does the egg of a bird.

Pathological Specimens.

M. GUBLER exhibited a sample of fibrous hypertrophy of Mery's glands (Cowper's).

Vaginal Tumor containing Portions of a Fetus.

M. JOBERT DE LAMBALLE presented a tumor about the size of a hen's egg, which had been removed from the vagina of a woman 41 years of age, in whom it had formed an impediment during labour. It was attached by a pedicle, and after delivery had been removed by ligature; and on examination was found to consist of a sac filled up with adipose matter, intermingled with which were found hair, a fragment of bone, a portion of maxilla with three teeth—a very large molar, an incisor, and a canine, of the size of adult age. In contact with these was a portion of the cranial bones. The summit of the tumor was covered with a cellular-adipose tissue, which proved to be omentum. Its walls consisted of three membranes—an external serous, a middle muscular, and an external mucous.

M. Jobert suggested that this tumor originated in an extra-uterine pregnancy; that the omentum had become adherent to the posterior wall of the vagina by inflammation, drawing with it a portion of omentum and of the broad ligament; and that

in the course of time it had perforated the wall of the vagina, whence it was finally protruded by the child's head during the last labour.

A Case of Obstruction of the Vas Deferens, accompanied by severe pain in the testicles, was related by M. DUNLAP.

Adipose Hamaturia (Milky Urine).

M. BAYER stated that he had, several years since, pointed out the frequent occurrence of this form of disease in tropical climates, especially in the Mauritius. M. Bayer related a recent instance thereof, accompanied with stricture of the urethra. The patient was a native of the Isle of Bourbon, 40 years of age. The milky character of the urine was at first concurrent with the presence of blood in that excretion. Occasionally the urine had been voided for short periods perfectly healthy. M. Bayer had sometimes seen a beneficial influence exerted in these cases by a residence in France.

Teratology.

M. Bayer exhibited a specimen of a supernumerary claw in a craw-fish.

M. DAVAINE submitted observations on the cyclopic malformations, with the following conclusions:—

1. That in cyclocephala the encephalon is always seriously deformed.
2. That its lesions are seated exclusively in the hemispheres.
3. That these lesions, though variable, generally consist in a diminution of the hemispheres, or their fusion into one lobe.
4. A rudimentary nose or snout exists in all these cases.
5. The eye may be present without an optic nerve.
6. The inferior region of the face (the tongue excepted) participates, more or less, in the atrophy of the upper parts.
7. The olfactory nerves may be distinct, or united into one cord.

ABSORPTION OF INSOLUBLE SUBSTANCES.

M. MEISSONIER, repeating the experiments of Osterlin, states that he has succeeded in detecting globules of mercury and particles of sulphur, charcoal, and starch, in the blood, and in the parenchyma of the organs. Having inflated the lungs of an animal that had been fed upon charcoal, and submitted very thin slices to microscopical examination, he says he detected the carbonaceous particles in the intervascular and interlobular spaces, while the same could not be found in other animals of the same species not fed on carbon. By examining the blood of the mesenteric vessels, particles of starch, readily detected by iodine, were met with.—*Archives de Médecine d'Utrecht, et L'Union Médicale.*

Hospital and Infirmary Reports.

WEST NORFOLK AND LYNN
HOSPITAL.CASE OF EXCISION OF THE HEAD OF THE
THIGH-BONE.

BY CHARLES COTTON, M.D., F.R.C.S.
Senior Surgeon to the West Norfolk and Lynn
Hospital.

[Continued from page 166 of Vol. ix. N. 3.]

Dec. 30th, 1859.—Jessie Bullen has improved in every way since the report of the 18th. She moves herself more easily in bed, but yet complains of pain in the back and loins whilst doing so. The hip wound is filled up with granulations, and nearly healed over. The limb operated upon lies comfortably extended on a pillow; but the other still remains awkwardly drawn up and contracted at the knee, resisting every attempt by friction and extension, as well as the endeavours of the patient, to straighten it. Takes the cod-liver oil occasionally. Eats and sleeps well.

1850, Jan. 2d.—Experienced pain and much uneasiness in the hip during the night; thinks she sat up too long and moved too much in bed yesterday. On examination it was found that through some inexcusable negligence the patient had been replaced in bed last evening without the usual outer support to the limb. The limb was much everted, and the tissues about the hip in consequence considerably stretched. A livid red streak was also observed coursing from the perineum over the front of the joint, and the groin was very painful and swollen. The faulty position of the limb instantly rectified, and splints loosely adjusted. Hot chamomile fomentations ordered to the groin. To remain perfectly quiet. The cod-liver oil to be discontinued.

4th.—Has been comfortable and easy; the red streak in the front of the joint has nearly disappeared.

12th.—Is cheerful and happy, and eats heartily, *but gains no flesh*, and the hip wound, though nearly healed over, has a fistulous communication with some burrowing abscess through which a rather profuse purulent discharge issues. Give again the oil. A glass of wine, and $\frac{1}{2}$ pint of porter, daily.

23d.—Has been much ruffled the last three or four days by a bed-sore over the sacrum, from which a subcutaneous passage was found leading to the back of the *opposite* hip, creating an impression of its being also

involved in disease. There is a recurrence of hectic irritation. The cheeks flush as formerly; the pulse is hurried, and tongue furred; the appetite bad, and she has evidently lost flesh; she, however, sleeps well, is free from cough, and the bowels act daily; there is some excoriation about the hip wound, but no pain. Placed on a water bed, and the sore over the sacrum further protected by an ox-bladder partially distended with water. Ordered a palatable sweetened mixture of quinine and sulphuric acid, and to leave off the wine and porter.

Feb. 6th.—Has improved in appearance; is easy and comfortable, but really gains no ground.

9th.—Again relapsing; much discharge from the sores. An abscess pointing below the left hip; ordered *sarsaparilla* and iodide of potassium, and any food or beverage she may wish for.

16th.—Looking better; appetite good. Bed sores easy, and improved in appearance.

22d.—There exists now, in addition to the sacral bed-sore, a large abscess below the left trochanter; the granulations of the right hip wound have given way, and the groin is oedematous and painful. The ex-haemating discharge has not yet made very great impression, owing to her being able to take freely generous and varied nourishment. Ordered *Syr. Papav. et Acid. Nitr.* Dil. p. r. n.

28th.—Hectic distress, and slow emaciation. Tumefaction and fluctuation in front of the joint operated upon.

March 6th.—Large abscess pointing in right groin.

14th.—Abscess dispersed, the discharge escaping through the hip wound.

April 6th.—Psoas and gluteal abscesses on both sides. The poor girl is quite resigned, and is slowly sinking.

16th.—Death.

Post-mortem.—Body emaciated to an extreme degree, the lower vertebral spinous processes denuded of skin, and the integuments over the sacrum and sacro-iliac articulations destroyed. Extensive caries of sacrum and lumbar vertebrae, and destruction of intervertebral substance, communicating internally and externally to each ilium, with the different abscesses. Lungs and other viscera healthy.

Appearances at the seat of operation.—Limb shortened about four inches; the extreme point of the femur discoloured and dead-looking, protruding at the outlet remaining at the hip wound. On reflecting the integuments, the end of the bone was found rising just above and upon the upper margin of the acetabulum, in a promising joint cavity, having the gluteal muscles at-

tached by tawny-looking ligamentous structure, serving in front and externally as the capsule of the joint; internally strong ligamentous and muscular attachments also existed.

The new joint end of the femur excited considerable interest; it was found much expanded out, and presented a considerable quantity of ossific reproduction, forming an admirable compensatory head to the shaft of the thigh-bone and miniature trochanters for the attachment of muscles; posteriorly it had suffered from pressure, and was somewhat damaged by caries. An attempt was made to straighten the obstinately contracted state of the left knee: this was effected after dividing the hamstring tendons, when a similar laceration of integuments to that reported during the life of the patient took place.

REMARKS.—In the notes already published in the *GAZETTE*, referring to this case, it is stated that the suffering and hopeless condition of the patient, and the favourable agency of chloroform, alone prompted the attempt at relief by means of excision of the luxated head of the femur, and that nine weeks of progressive amendment, and the greatly improved state of the girl's health, had not only seemed to sanction the operative procedure, but had even led to anticipations of further well-doing and the possible favourable termination of the case. This impression was much strengthened on the 18th of December, when nature spontaneously threw off the only apparently remaining portion of the diseased shaft, leaving the extremity of the bone in a condition similar to that observed in the stump shortly after amputation. From this period it will be seen, by the clinical reports now given, that the case continued to wear a most satisfactory aspect up to the 2d of January, when for the first time a disagreeable train of symptoms presented themselves at the seat of operation, following, if not caused by, provoking negligence. These, though succeeded by periods of amendment, failed to lull suspicions of lurking mischief, the patient remaining in a stationary condition, and the hip-wound continuing to discharge freely as if from some distant source of mischief. The misgivings entertained were soon after confirmed by the appearance of fresh manifestations of constitutional scrofula, placing the case beyond hope: from this time, Jan. 23d, the patient lingered in a state of calm resignation, until April 16th, when she sunk, emaciated and exhausted, after surviving the operation six months, during which she very frequently expressed her thankfulness for the relief and comparative comfort it had afforded her. The post-

mortem appearances at the hip demonstrated how admirably nature adapts herself to such emergencies, and confirmed the opinion previously formed, that failure in the present instance was alone attributable to the advanced stage of disease and *exhaustion* at the time the operation was undertaken.

The want of success, though not at all surprising under such unpromising circumstances, may possibly serve equally the exclusive advocate and the unmitigated opponent of the operation, as a subject for criticism; the one referring to the period of relief, prolongation of life, and the state of the parts operated upon in favour of the proceeding, but alleging from the result that the case was improperly selected. The other, perhaps not less captiously, insisting that the operation was altogether futile and inadmissible, and that the same amount of ease might have happened had it not been performed at all. In such a spirit of partizanship I take no share: neither do I presume from my limited observation to offer any positive opinion as to what cases are most fitted for the operation. On the score of severity or difficulty I certainly think no objection can be urged against it, having found the exposure, isolation, and sawing off the head of the bone a much easier proceeding than I had experienced in two resections of the elbow; and in another case, now in progress at the hospital, at which I assisted, the head of the femur (truly greatly absorbed) was readily reached and turned out of the wound, and the operation completed with the greatest ease. Though fully alive to the prejudicial influence of scrofulous cachexy, and inclined to believe that the operation is rather applicable to a necrosed than to a carious condition of the bone, I yet should feel justified in again resorting to excision (in the absence of visceral complication), even under like unfavourable circumstances, to those above reported, as well as in cases less advanced of *open* hip disease, attended with luxation and disease of the head of the femur.

The complete success attending Mr. Morris's case of excision of the head of the femur, reported in the *Medical Times* of Jan. 19th, 1850, led me to visit Spalding to gain a sight of the patient; and truly nothing could be more gratifying or unexpected. A period of about twelve weeks had sufficed to convert the case into a sort of talipes equinus: the wound was soundly closed, and free motion existed at the hip, the end of the femur being locked apparently against the upper rim of the acetabulum. The youth planted the toes and extremity of the sole of the foot with firmness upon the ground, and skipped and

hopped about with evident ease and satisfaction. Mr. Morris has some reason to be proud, and may be excused being somewhat didactic, his case having been pronounced, by a gentleman who omits no opportunity of writing in favour of the operation, one "*altogether the most satisfactory and interesting of those hitherto recorded.*" I cannot, however, but feel, that, whilst errors of diagnosis as to the position and state of the head of the bone occur even in able hands, and a doubt exists as to the fit cases in which the operation may be undertaken with propriety, it will be right to exercise the greatest caution to avoid a too ready and unnecessary resort to the operation, and I am strengthened in such a view by the recent observation of a formidable case of diseased hip, *attended with lussation*, and considerable sero-purulent effusion, where the joint has been tapped several times, and in which the head of the femur now lies quietly upon the dorsum of the ileum with no other inconvenience than a shortening of the limb and some considerable lameness.

Medical Trials and Inquests.

DEATH FROM CHLOROFORM IN SURGICAL OPERATIONS.

AN investigation took place last week, before Mr. Payne, coroner for London and Southwark, and a special jury, in the board-room of Guy's Hospital, respecting the death of Alexander Scott, aged 34, a police constable of the B division, who died from the effects of chloroform, while undergoing an operation for the removal of a portion of the right hand.

James Scott, of Creek-road, Deptford, stated that the deceased was his brother. In May, 1849, the deceased received an injury to the right hand, while on duty, by having one of his fingers bitten by a man whom he had taken into custody for creating a disturbance. The middle finger was soon afterwards amputated by a surgeon at Deptford, but deceased always complained of great pain in the limb. On Wednesday week, deceased was advised to apply at Guy's Hospital, with a view of having some operation performed to relieve him. Witness came to the hospital on Wednesday last, just after the operation had been performed, and then found his brother dead. By the coroner.—Had heard since the death that deceased had died under the influence of chloroform, taken by his own wish, as he (the deceased) could not bear the pain attending the operation.

John Lacy, dresser to Mr. Edward Cock, one of the surgeons, stated that he first saw the deceased on the morning of Wednesday last. Witness examined the right hand, and found that the second finger had been removed at the knuckle-joint. Mr. Cock was present, and every thing having been arranged chloroform was administered to the deceased by the machine, but not taking effect it was applied by a napkin. In about two minutes the chloroform had the proper effect. The operation was then commenced by Mr. Cock, when the deceased appeared to be fainting, and just as Mr. Cock had completed it the deceased appeared to be dead.

Mr. Edward Cock, surgeon to the hospital, said, the deceased was sent to him by a surgeon at Deptford for severe pain in the right hand. One of the fingers had been removed, and deceased suffered great pain at the stump. Witness found him to be a strong vigorous man. The bone was in a diseased state, as were also the nerves, producing very great tenderness of the arm and right side of the body. The only remedy was to remove the end of the bone and diseased nerves. The deceased came into the hospital to have the operation performed; when deceased said, "I hope, Mr. Cock, you will give me chloroform, for I cannot bear the pain." Witness informed him that he would rather not use it, and endeavoured to dissuade him from taking it; but the deceased added that he had made up his mind to have it administered to him. Witness always objected to the use of chloroform, for it could never be given without some degree of danger. The ordinary machine was used, and, as it had not the effect, witness directed that a napkin should be folded into the shape of a cone, which was applied with chloroform. The operation of removing a portion of the bone occupied one minute and a half, but before it was completed, the blood which was gushing out suddenly stopped, when witness directed Mr. Lacy to feel the pulse of deceased, and they then found that deceased had expired. *The Coroner.*—What was the cause of death?

Witness.—The chloroform, most undoubtedly. In this instance, a very small quantity had been used, not a *tenth part* of what had been administered in other cases. Witness could not account for the patient dying, and was certain there was no disease about him. So strong and powerful an agent was chloroform, that it could not be administered without some amount of risk and danger, and the penalty the public must pay for the alleviation from pain would be a death occasionally. A similar death occurred, about 12 months since, at St. Thomas's Hospital, and many

other deaths might be recorded. It might be used one or two thousand times, or more, successfully, and was of great assistance to the operator. *The public ought to know the danger and great risk attending its administration.* In many cases where chloroform had been used witness had waited with breathless attention for the recovery of the patient. *Witness strongly objected to its use.*

The coroner then summed up the evidence, and the jury returned a verdict of "Died from the effects of chloroform."

Medical Intelligence.

THE MEDICAL REFORM QUESTION. RAIL- LATING QUESTIONS OF THE NATIONAL INSTITUTE.

Notice and Schedule addressed by the Council of the National Institute to the General Practitioners of Medicine, Surgery, and Midwifery in England and Wales.

Hanover Square Rooms,
4, Hanover Square,
June 24th, 1880.

SIR,—Five years ago the sentiments of nearly five thousand general practitioners were recorded in favour of a new and independent incorporation of the general practitioners in this kingdom, and recent circumstances have rendered it incumbent that the opinions of the same class of the profession should be again taken on the necessity and expediency of this measure.

Having, by repeated communications with the Secretary of State for the Home Department, and with the Council of the College of Surgeons, fully ascertained the impracticability of so altering the constitution of the College as to render its arrangements acceptable to the general practitioners throughout the country; and since any alteration that could be effected in the College of Surgeons would not meet the just complaints of the large number of medical men practising legally, although not members of the College, the Council of the Institute consider that any further attempts to open the College must prove fruitless, as respects the main objects of medical reform, and that the only means of improving the status of the general practitioners, and restoring peace to the profession, would be by the establishment of an independent college, giving to the general practitioners the full control of the education of their members in medicine, surgery, and midwifery, and enrolling, as

one body corporate, in an institution of their own, every general practitioner of the kingdom.

I have the honour to be, sir,
Your obdt. humble servant,
GEOFFREY ROSS, Secretary.

Objects of the National Institute of Medicine, Surgery, and Midwifery.

The principal objects of the Institute are, to maintain an effective organization of the general practitioners—to expose, discourage, and suppress, by registration, and every other practicable means, illegal and unqualified practice—to employ all legitimate means for the purpose of urging upon the Government and the Legislature the claims of the general practitioners of this country to corporate rights—to promote a high standard of education and qualification, with a satisfactory test, by efficient examination, for every individual authorized by law to practise medicine, surgery, and midwifery—and to form, irrespective of the special colleges, an Institution comprising within itself the entire range of medical and surgical knowledge.

The body of general practitioners includes—Every gentleman who was in practice previous to the 1st of August, 1815; and every Licentiate of the Apothecaries' Society; also every Fellow or Member of any Royal College of Surgeons in England, Ireland, and Scotland; every Doctor or Bachelor in Medicine, of any University of the United Kingdom; and every Fellow or Licentiate of any College of Physicians of the United Kingdom,—in actual practice as a general practitioner.

NOTE.—According to the principles of the National Association and of the National Institute, the dispensing of medicines ought not to constitute a disqualification for offices of honour and emolument. The dispensing of medicines must at all times rest with the individual, and must depend upon the circumstances under which he may happen to be placed with his patient and the public.

Schedule.

Are you desirous of a separate incorporation of all the qualified general practitioners of medicine, surgery, and midwifery in an independent college of their own, upon the elective principle, comprising within its own limits the entire range of medical and surgical science and practice, with the control of the education and examination of future members?

Date

POOR LAW UNIONS.

ON Saturday last, a Parliamentary return was issued, showing that in 1849 the sum of £78,424 16s. 7d. was expended in the salaries of medical officers, and £20,529 in the salaries of schoolmasters and school-mistresses; making a total of £98,953 16s. 11d. under the head of Poor Law Unions, in England and Wales.

GERMAN HOSPITAL, DUBLIN.

ON the 27th ult., the annual court of the governors of this hospital was held at the London Tavern. The report spoke favourably of the progress of the institution during the past year; the income having enabled the committee, after paying off the expenses of the institution, to pay the £500 which remained due for the premises, and to invest £1,000 in the Three-and-a-quarter per Cents. At the anniversary dinner the large sum of £1,847 18s. 7d. in donations, and £80 1s. subscriptions, was realised, including contributions from the Emperor of Austria, the King of Bavaria, the Senate of the free city of Frankfort-on-the-Maine, and his Royal Highness the Duke of Cambridge. The number of patients had greatly increased: the in-patients during the year numbering 474, of which 21 were accidents; and the number of out-patients being 2,895: making a total of 10,484 patients relieved since the opening of the hospital in 1846. The income during the year had amounted to £2,831 10s. 9d., in addition to the £1,400 for the sale of the garden; and the expenditure amounted to £2,866 19s.: leaving a balance of £144 11s. 9d. The expenditure included the purchase of £1,000 stock. This report was adopted on the motion of Dr. Sieveking.

THE HARVEIAN ORATION.

ON Saturday last, according to ancient usage, this oration was delivered at the Royal College of Physicians, Trafalgar-square, in the presence of Dr. Paris, President of the College, several members of the council in their robes of office, and a numerous assemblage of other distinguished members of the medical profession. The oration, which was in Latin, was delivered by Dr. Wilson, of St. George's Hospital, and drew forth repeated marks of approbation from the audience. Allusion was made, among other topics, to the ravages of cholera during the past year, and the degree of skill, perseverance, and philanthropy exhibited by the medical profession during that trying period. The new-fangled doctrines of hydropathy, homoeopathy, and mesmerism, were also touched upon and criticised. The learned doctor did not omit the usual tribute of respect

to the genius of Harvey, for his great discovery.

MEMOIR OF THE LATE DR. S. A. BARDSELEY, OF MANCHESTER.

WE recently recorded the death of this excellent provincial physician, and we here subjoin a few particulars regarding his life and professional progress.

Samuel Argent Bardsley was born at Melvedon, in Essex, on the 27th April, 1764. When in his fifteenth year he was apprenticed to a respectable surgeon in Nottingham. At the termination of his apprenticeship, at the age of 21, he continued his medical studies in London, Edinburgh, and Leyden, at which latter university he graduated in the year 1789. It was the first idea of the deceased to settle in London, but he was diverted from this intention, and for two or three months resided in Doncaster, with the view of practising as a physician in that town. Towards the decline of 1790, however, the year succeeding that of his graduation, circumstances rendered an appointment to the Manchester Infirmary open to him, and he was finally induced in November of that year to take up his residence in that town. Hereupon, his election as physician to the infirmary ensued, and for thirty-three years the deceased was actively and zealously engaged in the performance of these responsible duties which attach to such an office. During the whole of this period he constituted the very model of an hospitable physician, both as regards the scientific direction of his medical observations, and the warm-hearted benevolence and cheerfulness with which his services consoled the objects of his care. He resigned this appointment on the 4th of August, 1828. From the period of Dr. Bardsley's relinquishment of the medical duties of the infirmary, he gradually ceased to undertake the care of private patients; so that, in fact, at the time of his decease, he had been for nearly twenty-seven years a retired physician. Early in May last, he left Manchester, and after passing one week in Cheltenham and another in Leamington, he went up to London, and remained there for a week apparently in his best health. On the 24th he left the metropolis, to pay a visit to a friend near Hastings. The day after his arrival, he complained of slight indisposition, as if he had taken cold; feverish symptoms ensued, which, continuing unabated, terminated in his death on the 28th ult. He sank gradually, with little or no pain, in a state of very imperfect consciousness. Dr. Bardsley was a man of uncommon powers and attainments. Though possessed of no remarkable depth or originality of mind, there was yet a keen sagacity and accuracy

of observation, that, to a practical physician, were not probably of less importance. His reading, both medical and general, was extraordinary, and there were few facts upon which a singularly retentive memory did not enable him to shed light. In early life he published a valuable and useful volume of "Medical Reports," which to this day ranks in the standard literature of the profession. He also wrote several papers published in the Manchester Philosophical Society's Transactions, and contributed to the medical journals of the day several papers upon topics of practical interest. His body was privately interred in the family vault at St. Saviour's, Chorlton-upon-Medlock, it being conformable to the express injunctions of his will that his funeral should thus be conducted.

THE INFLUENCE OF THE MIND ON DISEASE. THE GREAT EFFICACY OF SUGAR OF MILK, WHEN PRESCRIBED UNDER THE FORM OF HOMŒOPATHIC GLOBULES.

SOME genuine homœopathic globules were lately submitted to chemical analysis, under the following circumstances. A lady who had been suffering from chronic gastric irritation, and who could get no rest at night, swallowed *three* of the globules by the advice of a homœopathic friend, who assured her they would procure refreshing sleep. In about two hours after having taken them, she fell into a sound sleep, and rested well for the first time for many weeks. The good effects were of course ascribed to the globules.

The globules were white,—smaller than millet-seeds, and three of them (*i. e.* the dose taken) weighed 0·04 gr. or about one twenty-fifth part of a grain. The paper represented that they were globules of *Nux vomica*. When heated on platina, they burnt with the smell of burnt sugar: they were quite soluble in hot water, solution perfectly neutral, and the tests of Trommer and Moore showed that sugar (glucose), was the principal if not the only constituent. The powder tested by the nitric and iodic acids was unchanged: it gave not the slightest indication of morphia or brucia. The most delicate test for strychnia, *i. e.* sulphuric acid and chromate of potash, shewed that not a particle of that alkaloid was present.

It may be said that the principles of *nux vomica* were in the globules, but in too small a quantity to admit of detection by chemical processes. If this be so, how can it be shown that there was any *nux vomica* in the globules at all? No assertion of this kind can be received without satisfactory proof, or we may as well all back at once to the days of super-

stition, and put faith in amulets or charms. If chemistry fail to reveal the active constituents of homœopathic globules, how are those containing arsenic to be distinguished from those which contain sulphuric acid; or how does a homœopathic practitioner, receiving these globules from his druggist in implicit faith, know that he is not, by some mistake, giving his patient *cayenne pepper* instead of *nux vomica*. A slight shake of the box, containing sets of the globules, will at once confound antimony and opium, arnica and arsenic; and in fact, but for their being, as we shall presently prove, quite innocent of the results ascribed to them, globules of the most dangerous medicines might be substituted for others which are comparatively inert.

The first element of homœopathic therapeutics is, therefore, that a man does not know, and has no means whatever of ascertaining, the nature of the medicine which he is prescribing! He believes his druggist, and his patient believes *him*, when he says she is taking arnica and not arsenic: and there is an end of the matter. Prescriber and patient must be equally credulous, assuming that the former is acting *bonâ fide*, and not attempting, like some of the craft, to CURE his patients by giving them formidable allopathic doses of morphia and calomel, under the name of homœopathic powders.

There is, however, another point of view in which this case deserves to be contemplated. Admitting that the three globules contained half their weight of some narcotic, what is the medicine which in the dose of the *fiftieth part* of a grain will procure a sound sleep of six or seven hours duration?

But these globules were marked *nux vomica*, of which the active ingredient is strychnia, an alkaloid that forms about 1-200th part by weight of the powder. On the assumption that *nux vomica* formed the 50th part of a grain in the three globules, the quantity of strychnia therein contained would be only the 1-10,000th part of a grain. Can any rational person believe that this dose of strychnia, mixed with the 50th part of a grain of sugar of milk, would produce in an adult a sound sleep of seven hours duration? If so, he is bound to believe in the cure of diseases by amulets and charms. But it may be said, what produced the sleep? The answer to this is very simple—the patient was subsequently made to swallow, *without being aware of it*, a similar dose of the globules; and on this occasion, she passed as restless a night as when she had been under allopathic treatment! It was not therefore the globules, but the impres-

sion produced on her mind and feelings, which gave rise to sleep.

The following is another curious case communicated to the writer by an eminent physician, now practising in London. He says, I met R. C. at Florence, whither he had come from some of the baths in Germany. He informed me that he had suffered martyrdom from indigestion and confinement of bowels, but that the latter had been quite cured by a homœopathic physician, whom he accidentally fell in with in his travels, and who had proffered his advice, unasked, to one who had no previous faith in his system.

This gentleman, as he stated, without enjoining any particular rules of diet, merely gave him *three small pills*, and assured him that each of them would infallibly keep his bowels in a *regular state, causing an evacuation once a day, for a month*. R. C. told me that the event perfectly bore out the prognostication, and that at the end of three months a habit of regularity was completely established!

The nature of these pills was not determined by analysis; but is there any one acquainted with the physiology of man, and the nature of drugs, who could believe that three small pills would exert the powers here assigned to them? We think not.

Homœopathic therapeutics fail as much when submitted to the balance and chemical analysis, as when examined by the light of reason. They rest entirely upon hypothesis. Nothing physical can be proved with respect to them. A lately deceased homœopathic physician remarked, when no trace of sulphur was found by chemical tests in his sulphur-globules, that in his opinion *the matter became spiritualised by trituration!* In what respect does such an hypothesis as this differ from the curing of ague by suspending a written charm to the neck? or from curing warts by cutting notches in an elder stick.

The homœopathic practitioner wishes us to believe that the power of medicine is increased by the diminution of dose, and that the power acquires its maximum when no chemical test can show the presence of the medicine in a globule of sugar. Further, that substances like charcoal, which have no action in large doses, become very energetic when the dose is so reduced that no charcoal can be discovered. This it will be seen is simply asking us to believe that a part is greater than the whole, and to disbelieve all that experience has hitherto taught us.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of

medicine, and received certificates to practise, on Thursday, 27th June, 1860:—John Thompson, Cowpen, near Newcastle-on-Tyne—Crosby Leonard, Bristol—Henry Briggs, Halifax, Yorkshire—George Pain, Salisbury—William Felliter, Wareham, Dorsetshire—Thomas Andrews Chaldecott, Montague Place.

Selections from Journals.

UTERINE NEURALGIA.

M. VALLEIX has pointed out a class of cases in which the cervix uteri, usually insensible, becomes the seat of the most acute suffering of a neuralgic nature, and has pointed out the diagnostic distinctions between these and cases of painful inflammatory congestion of that organ.

This neuralgic form of disease is frequently met with, but is not often recognized. In all the cases which have come under M. Valleix's notice, the affection has been accompanied by pain following the course of the lumbo-abdominal nerves. He, therefore, regards the neuralgia of the cervix as part of the more extensive lumbo-abdominal neuralgia. This feature is of importance in reference to the diagnosis of neuralgia from other pains of the cervix uteri.

The subjects of this neuralgic affection present all the characters of sufferers from chronic uterine congestion, with which disease the former is almost always confounded. The pain is much augmented at the menstrual period, producing dysmenorrhœa. The vaginal discharge which occurs in these cases is analogous to the increased secretion from the mucous membrane of the eyelids in certain affections of the trifacial nerve. They are both functional disturbances originating in disordered nervous influence.

Careful exploration is of the first importance to its detection. The neck of the uterus will be found tender to the touch, often so to a great degree, the tenderness being most acute at the sides of the cervix, while the anterior and posterior surfaces are free. The cervix is of its ordinary form and size.

On examining the abdomen and loins, a neuralgic pain will be detected in the hypogastrium a little beyond the middle line on one side, most frequently the left only. Along the course of the first pair of lumbar nerves will be discovered other points, more or less acutely painful, and more or less isolated. The painful point always corresponds with the seat of pain in the uterus.

The chief diagnostic features are, the degree and isolation of the tenderness, the intermittent character of the pain, and the occurrence of the neuralgia of the abdomen and loins.

The treatment adopted by M. Vallin has been: Misture to the hypogastric region, cauterization of the cervix, and narcotic injections, with absolute rest and general treatment.—*L'Union Médicale.* x

OBITUARY.

On the 28th ult. at Holloway, after a few hours' illness, Dr. Carrington, for several years resident medical officer to the Holloway and North Islington Dispensary.

On the 12th of April, at Accra, western coast of Africa, in the 31st year of his age, Frederick Burton Phillipson, Esq., Assistant Surgeon to the Forces, third son of the late Major George Burton Phillipson, of the Hon. East India Company's Service.

NOTICES TO CORRESPONDENTS.

Communications have been received from Dr. Barnes, Dr. Routh, Dr. Bird, Mr. R. H. A. Hunter, and Mr. Jennette. These will be inserted with as little delay as possible.

We regret that we are still obliged to postpone the insertion of several papers which are in type.

Lectures.

LECTURES

ON INFLAMMATION,

(Delivered in the Theatre of the Royal College of Surgeons of England).

BY JAMES PAGET,

Professor of Anatomy and Surgery to the College.

LECTURE V.

Effects of inflammation on the part in which it is seated; their generally destructive character—Softening of inflamed parts, as of brain, bones, ligaments, &c.—Fatty degeneration of inflamed parts, as in the liver and heart.—Interstitial absorption of inflamed parts, as seen in bones, cartilages, glands, &c., and in the spontaneous opening of abscesses—Ulceration; ejection of tissues disintegrated after degeneration; supposed effects of corrosion and solution of tissues by ichorous discharges.—Gangrene.

THE account of the results of inflammation in the part in which it has its seat will include the chief among its second class of effects—the destructive effects. For I believe that nearly all the effects of inflammation are injurious, if not destructive, to the proper tissues of the part in which it is seated. All the changes I shall have to describe are characteristic of defective or suspended nutrition in the parts: they present varieties of degeneration, modified by the circumstances in which they have occurred, and especially by this,—that while the changes of the proper tissues of an inflamed part are making progress with all the characters of degeneration, the lymph-products of the inflammation may be in process of either development or degeneration in their interstices, or on their free surfaces.

One of the most common effects of inflammation in an organ is a more or less speedy *softening* of its substance: and this is due not only to infiltration of it with fluid, but to a proper loss of consistency, a change approaching to disintegration, of which, indeed, it is often the first stage. Of such mere softening, some of the best examples are in the true inflammatory softening of the brain and spinal cord, in which the softened part is usually found to consist of spoiled nervous substance, together with more or less abundant granular

products of inflammation. Such softening also may be found in the lungs: the peculiar brittleness and rottenness of texture, which exists with the other characters of hepatization, are evidently due to changes in the proper tissue, more than to incorporation of the products of inflammation. In staphyloma of the cornea, similar softening ensues in connection with the opacity and other changes of appearance. But, perhaps, the most striking instance of softening in inflammation (and it is the more so because the softening probably precedes the other evident signs of inflammation*) is to be found in bones. One may generally notice that an acutely inflamed bone is soft, so that a knife will easily penetrate it. Thus it may be found in the phalanges of the fingers when they partake in deep-seated inflammation, and thus, sometimes, in the neighbourhood of diseased joints. The change depends partly on an absorption of the earthy matter of the bone, this constituent being removed more quickly, and in greater proportion, than the animal matter; but the entire material of the bone is softened.

The softening of bones may permit of peculiar subsequent changes, especially of their swelling and expansion. Thus, in a remarkable case communicated by Mr. Arnott to Mr. Stanley, after excision of the corresponding ends of the radius and ulna, inflammation ensued in the shaft of the humerus, and after four months the patient died. The end of the inflamed humerus was full-red, and swollen, with an expansion or separation of the layers of its walls. And the case showed well the coincidence of absorption and of enlargement by expansion; for though the diseased humerus was thus enlarged, and contained more blood than the healthy one, yet it "was found not to weigh so much by half."†

Similar expansions of bone, with all the characters of inflammation, and such as could not have happened without previous softening of the tissues, form part of the many swollen and enlarged bones which are common in all our museums.‡ Doubtless, in many of these cases, the disease has been of very slow progress, and the separation of the several layers of the compact bone, which the specimens display, must be ascribed to their gradually altered form, as they have grown about the enlarging blood-vessels and interstitial inflammatory deposits. But in other cases the expansion has in all probability been more rapid, the softened bone yielding and extending, as

* See Kuss, as quoted by Virchow, in his *Archiv.*

† Mr. Stanley's Illustrations, pl. i. fig. 4, 5, 6.

‡ In the College Museum, No. 593 to 600, and 3062 to 3064; and in the museum of St. Bartholomew's, Series I. Nos. 55, 94, 113, 114, 115, 120, 197, 198, &c.

the naturally softer tissues do, in an inflammatory swelling.

The characters of a bone thus expanded are easily discerned. Its substance may be irregularly cancellous or porous; but the most striking change is a more or less extensive and wide separation of the concentric laminae of the walls of the bone, so that the longitudinal section of the enlarged wall appears composed of two or more layers of compact tissue, with a widely cancellous tissue between them: and these layers may sometimes be traced into continuity with those forming the healthy portion of the wall. Usually, the separated layers are carried outwards, and the bone appears outwardly enlarged; but sometimes the inner layers of the wall are pressed inwards, and encroach upon the medullary tissue. In the first periods of the disease, the cancellous tissue between the separated layers of the wall has wide spaces, which are usually filled with a bloody-coloured medulla: but this tissue, like the often coincident external formations of new bone, appears to have a tendency to become solid and hard; and its fibrils and laminae may thicken till they coalesce into a compact ivory-like substance, harder than the healthy bone.*

Again, for examples of softening in inflammation, I may adduce the softening of ligaments, such as permits that great yielding of them which we see almost always in cases of severely inflamed joints. This is not from mere defective nutrition; for it does not happen in the same form, or time, or measure, in cases of paralysis or paraplegia engendering extreme emaciation. Neither is it from the soaking of the ligaments with the fluid products of the inflammation; for it does not happen in the abundant effusions of the slighter inflammations of the joints; and when ligaments are long macerated in water they yet retain nearly all their inextensibility. It appears to be a peculiar softening, or diminished cohesion, of the proper tissue of the ligaments, the result of a defective nutrition combined with infiltration of inflammatory products.

We may see such changes in the ligaments of all joints; in the hip, in the cases of spontaneous dislocation occasionally seen, independent of suppuration or ulceration of the parts belonging to the joint; in the wrist; when the ulna after disease becomes so prominent; in the vertebrae, especially in the ligaments of the atlas and axis. But we see the effects of this softening best in diseased knee-joints and elbow-joints; and in all these cases we may often observe an

interesting later change when the inflammation passes by. The ligaments softened during the inflammation yield to the weight of the limb, or perhaps to some muscular force, and the joint is distorted. Then the inflammation subsides, the normal method of nutrition in the joints is restored, the elongated ligaments recover their toughness, or are even indurated by the organization and contraction of the inflammatory products deposited in them; but they do not recover their due position; and thus the joint is stiffened in the distortion to which its ligaments had yielded in the former period of inflammation. In the crowds of stiff, distorted, and yet not immovably fixed joints that one sees as the consequences of inflammation, these changes must generally have happened to the ligaments:—first softening and yielding—then recovering, with induration, and perhaps some contraction, due to their atrophy and the organization of the inflammatory deposit. The cases are aggravated by similar changes in the adjacent parts; for the stiffness of such joints is not due to the ligaments alone; all the subcutaneous tissues are apt to be adherent and indurated.

The softening of the tissues of an inflamed part may be regarded as one of the instances of degeneration in the inflammatory process; and its diversity from ordinary degenerations may be ascribed to the simultaneous infiltration of the inflammatory product, and perhaps to some other circumstance we cannot at present trace or guess. But a more general and unmixed form of degeneration may, I think, be occasionally observed in the tissues of inflamed parts—namely, fatty degeneration; and this in such a manner, as to make it probable that the degeneration takes place even during the inflammation. Thus fatty degeneration of the hepatic cells appears an usual coincident of the form of inflammation which produces the so-called "brawny" liver. I think, too, that I have seen fatty degeneration of the muscular fibres in inflammation of the heart; especially in a recent case, in which the heart was punctured with a needle, and the patient died four days afterwards. The portion of the heart near the needle was more degenerate than the rest of its substance. So, also, in some instances of acute ulceration of cartilage, I have found that a fatty degeneration of the contents of the cells, together with similar degeneration or disappearance of the nuclei, constantly precedes the removal of the whole substance of the cartilage.* I am inclined,

* Abridged from the *Pathological Catalogue of the College*, vol. ii. p. 97.

* Similar observations are made by Dr. Redfern, especially in the third case of his excellent

therefore, to believe that this method of degeneration may occur not unfrequently in inflammation of certain parts, and may be, like the softening last described, a principal constituent of the changes preceding their complete absorption.

Both the foregoing degenerative changes in inflamed parts are favourable to complete removal by *absorption*, in which we find another example of the destructive effects of inflammation. And this absorption, which in many inflammatory conditions is a peculiarly rapid event, may affect at once the proper elements of a part, its bloodvessels, and the inflammatory products that may have been previously deposited among them.

I shall refer here only to that which has been called *interstitial absorption*: to the removal of parts from within the very substance of the tissues, as distinguished from the removal by the ejection of particles from the surface, of which I shall next speak as occurring in *ulceration*.

We may believe that such degenerations as I have just described usually precede this interstitial absorption of parts; but we cannot be quite sure of it, because we cannot see the parts immediately before absorption; or, rather, because we cannot be sure that what we see was to have been very soon absorbed. But, as I stated in the last lecture, we are justified in holding that no absorption of the living tissues can take place without previous change or degeneration of that which is to be absorbed. And we may the more certainly believe that, in the interstitial absorption which takes place in an inflamed part, degeneration and disintegration of its tissues always ensue before they are, as the expression is, "taken up," from the observation that the degenerative changes, which I have just described, are sometimes evidently the precedents of absorption. Of such interstitial absorptions of inflamed parts, we find well-marked instances in that form of ulceration of articular cartilages in which the deeper portion of the cartilage is removed, together with the adjacent osseous layer covering the head of the bone; for here we can hardly suppose that the disintegrated particles are cast out, whatever they may be in the superficial ulceration of the same tissue. Such interstitial absorption is seen, too, very well in inflamed bones. The head of a bone may be scarcely enlarged, while its interior is hollowed out by an abscess; what remains of the bone

may be indurated, as by slight and tardy inflammation, but so much of the bone as was where now the abscess is, must have been inflamed and absorbed. Here, too, the evidence of absorption is completed by the similar excavations formed in bones within which cysts and tumors grow; for in these cases no other removal than by absorption seems possible.

To similar absorption of inflamed tissue we may refer the wasting and deformity that we notice in the heads of bones that have been the seat of chronic rheumatism. The best examples of this are in the head and neck of the femur; and the retention of the compact layer of bone, covering in the wasted cancellous tissue of the shortened neck and flattened head, is characteristic of interstitial absorption, as distinguished from ulceration, by which the cancellous tissue is commonly exposed. In these cases of chronic inflammation of the bones, we may notice, also, an appearance of degeneration that precedes a peculiar mode of absorption. While the articular cartilages are passing through the stages of "fibrous degeneration," and are being gradually removed, the subjacent bone is assuming the peculiar hardness which has been termed "eburnation," or "porcellaneous" change. Now this change is effected by the formation of very imperfect bone,—of bone that has no well-formed corpuscles; and resembles the result of mere calcareous degeneration rather than of a genuine ossifying induration. And its character as a degeneration is further declared in this; that it is prone to the destructive perforating ulceration, which often gives a peculiar worm-eaten appearance to the bones thus diseased.*

With these changes in rheumatic bones we may also cite, as instances of absorption during inflammation, the changes which Mr. Gulliver† first described as apt to ensue after injuries about the trochanter of the femur. In such cases, without any appearance of ulcerative destruction, the head and neck of the femur may waste by absorption, the neck becoming shortened, and the head assuming a peculiar conical form. We might regard these effects as a simple atrophy, if it were not that they are like the effects of the more manifest inflammation in the rheumatic cases, and

* A change, which appears to correspond with the eburnation of bone, is described by Mr. Tomes, as occurring in the part of a tooth which lies just beneath a carious cavity. In both cases the induration might suggest that it is calculated to retard the progress of the disease, but we have no evidence that it does this in an effective manner; and in the case of the bones there is every appearance that the destruction is most rapid where there is most induration.

† Edinburgh Med. and Surg. Journal, vol. lxxi. — The change is illustrated in No. 3512 in the College Museum.

essay on "Abnormal Nutrition in Articular Cartilages." Perhaps, also, we ought to classify with the degenerations that may ensue in the proper tissue of an inflamed part, the ossification of the laryngeal cartilages when involved in inflammation, and the fibrous structure acquired in slightly and long inflamed muscles.

that the existence of inflammation during life is often declared by the symptoms following the injury.

Again, other examples of the absorption of inflamed parts, or of parts that have been inflamed, are presented in the wasting of glands after inflammation; as in cirrhosis of the liver, in some forms of granular degenerations of the kidney, in the indurated and contracted lung after pneumonia.

No doubt, in these cases, the reduction of the organ depends, in a measure, on the contraction of the diffused inflammatory product, as it organizes; but in many cases the quantity of new tissue is extremely small (it is so in the shrivelled granular kidney); and, in all the cases, we may well doubt whether the contraction of organizing lymph would produce such extensive and uniform absorption of the proper substance of an organ, if there were not a previous condition favouring the absorption. The most probable explanation of these cases seems to be, that as, in the early periods of the inflammation, the softening and the degeneration of the inflamed tissues coincide with the production of the lymph; so, as the inflammation subsides, and subsequently, the absorption of the degenerated tissues may often coincide with the full organization and contraction of the lymph. And it is altogether most probable that these events are independent though concurrent; that each occurs as of itself, not as the cause or consequence of the others.

To all these cases must be added the fact of the absorption of the blood-vessels, and other accessory apparatus, of the inflamed tissues. The absorption of the absorbents themselves must coincide with that of the tissues. What a problem is here! These, that had once been the apparatus maintaining life, that had been adjusted to its energy and fashion, now, as it fails, remove themselves in adaptation to its failure. How can this be? We can only guess that its method is just the reverse of the method of formation; that, as in growth the blood-vessels and lymphatics follow in the course of evolution of the growing parts, opening and extending into each new part as it forms, so, in decrease, they follow, and closing-in harmoniously with the general involution, mingle their degenerate materials with those of the tissue, and are absorbed by the nearest remaining streams of blood.

Once more; not only the original elements of the tissues may be absorbed, but, even more rapidly, the new-formed products of inflammation. We have the best example of this, as well as, indeed, of many of the facts which I have been mentioning, in the spontaneous opening of a common

abscess; which, though it be so common a thing, I will venture to describe here.

Let us suppose the case of an abscess formed in the subcutaneous tissue; of such an one as may have had its origin in lymph infiltrated through a certain area of the tissues, and forming therein a hard circumscribed inflamed mass. Of this lymph we may suppose the greater part degenerating into pus. It may begin to do so at a central point,—the point at which the conditions of nutrition are the most impaired: or the suppuration may begin at many points at once, and, thence extending, the several collections of matter may be fused together. Sometimes masses of the infiltrated and softened tissue are thus detached and cast loose in the cavity of the abscess (as in these specimens).^{*} But at length we may suppose all the central portion suppurated, while the peripheral part, as happens usually in chronic abscesses, may be more organized, may acquire blood-vessels, and may thus assume the character of a granulation-layer, and form the proper wall of the abscess.

The pus of such an abscess as this will contain, probably, besides its proper constituents, some of the disintegrated tissue of the part in which it has its seat. We cannot, indeed, be quite sure of this; for it may be, that while the lymph is being formed, or being converted into pus, the proper tissue of the part may be undergoing absorption; and although, in the pus of abscesses thus formed, we often find abundant molecular and granular matter, yet this may be the debris, not of the tissue, but of the lymph-cells or pus-cells, or of the fibrine which may have coagulated with the lymph-cells. We cannot, I think, be sure on this matter; but we may be sure that the circumscribed portion of tissue, in which such an abscess as I am describing has its seat, degenerates, and is either absorbed, or else disintegrated so as to mingle more or less of its substance with the pus.

In such an abscess, moreover, we often find a layer of cells, spread out like a thin yellowish-white membrane, on the interior of the wall. They are only like lymph-cells or pus-cells, not yet mingled with the rest of the contents of the abscess: but they have been made to seem more important by being called a 'pyogenic membrane,' and by its being sometimes implied that it is their work to secrete the pus. But the existence of such cells is far from constant in abscesses, and we cannot suppose a special membrane necessary for the formation of pus, while we see the best examples of it formed on

* College Museum, 112, 114.

granulating wounds, and on mucous surfaces, which have no such 'pyogenic' membrane.

The abscess thus formed has a natural tendency to open, unless all the inflammation in which it had its origin subsides. Inflammation appears to be essential to the spontaneous opening of abscesses; for, where it is absent, the matter of chronic abscesses will remain, like the contents of any cyst, quiet, for weeks, or months, or years; and when in chronic abscesses, or in cysts, inflammation ensues through the whole thickness of their coverings, it is usually certain that their opening is near at hand. This difference between acute and chronic abscesses makes it very doubtful whether the inflammation of the coverings of an abscess can be ascribed to any local influence of the pus. But to whatever it may be ascribed, we may refer to this inflammation the comparatively quick absorption of the integuments over the collection of matter: and thus the fact, however we may account for it, that the integuments are more prone to inflammation, and more actively engaged in it, than the other tissues about an abscess are, may be used to explain the progress of matter towards the surface. Possibly—though this I think is much less probable—the tissues between an abscess and the surface may, after the degeneration which accompanies their degeneration, be disintegrated, and may mingle their molecules with the purulent contents of the abscess. But in favour of the belief that they are absorbed we have the evidence of analogy; for just the same thinning and removal of integuments takes place when they inflame over a chronic abscess, with a thick impenetrable cyst, or over an encysted or even a solid tumor.* Here absorption alone is possible; and the cases are so similar to the ordinary progress of abscesses, that I think we may assign all the changes of the integuments over these to the same interstitial absorption.

As the absorption proceeds, the integuments grow not only thinner, but softer, and more yielding. And this softening is worth notice, because one might suppose that as pus accumulates; so the integuments over it would become tenser and more resisting. It is, probably, in great measure, such a softening as I have already spoken of in degenerating inflamed parts; but it may be also due, in some degree, to such a change as that to which Mr. Hunter refers as "the relaxing or elongating process." He used to show this specimen, and say of it in his lectures,

"This preparation represents the front of a chest which contained an aneurism of the aorta; and here, on the right side, you see an instance of the elongating process, the cartilages being bent outwards, or elongated, to adapt themselves to its figure." Of the same process he says elsewhere,* "Besides these two modes of removing whole parts, singly or together [that is, besides the interstitial and the progressive absorption], there is an operation totally distinct from either; and this is a relaxing and elongating process carried on between the abscess and the skin, and at those parts only where the matter begins to point. It is possible that this relaxing, elongating, and weakening process, may arise in some degree from the absorption of the interior parts; but there is certainly something more, for the skin that covers an abscess is always looser than a part that gives way from mere mechanical distension, excepting the increase of the abscess is very rapid.

"That parts relax or elongate without mechanical force, but from particular stimuli, is evident in the female parts of generation, before the birth of the fœtus; they become relaxed prior to any pressure. The old women in the country can tell when a hen is going to lay from the parts becoming loose about the anus."

I have quoted the whole passage, because I believe that more recent researches have done nothing towards either improving the description or explaining the fact, except in so far as they make it probable that the change is due in a measure to the inflammatory softening of the pointing skin.

While these changes of degeneration and removal, of softening and relaxing, are ensuing in the cutis over such an abscess as I have described, we commonly notice that the cuticle separates, leaving the very point, or most prominent part, of the abscess bare. The cuticle is not raised as in a blister, but peels-off like dead cuticle; and we may believe that it is dead, partaking in the failure of nutrition in which all the parts over the abscess are involved, and being removed as a dead, not as a merely degenerated, part: for thus cuticle is always removed.

At length, after extreme thinning of the integuments, they perish in the centre of the most prominent part.—Sometimes the perished part becomes dry and parchment-like, with a kind of dry gangrene; but much more commonly a very small ordinary slough is formed, and the detachment of this gives issue to the purulent matter. The discharge is usually followed by a

* As in No. 121, College Museum.

† College Museum, No. 122; and Catalogue, vol. i., p. 53.

* On the Blood, &c. Works, vol. iii. p. 477.

more or less complete cessation of the inflammation in the integuments, and then the wall of the abscess, having the character of a cavity lined with healthy granulations, heals.

Such appears to be the ordinary course of an abscess; and I venture to hope that the numerous principles of inflammation that it illustrates will justify my having used so much time in describing it.

I proceed now to the consideration of *Ulceration*, as one of the effects produced by inflammation in the proper tissue of the inflamed part.

I need hardly say that, ever since Hunter's time, confusion has existed in the use of the terms employed for various kinds or methods of absorption and ulceration. Of all that Hunter wrote, nothing, I think, is so intricate, so difficult to understand, as his chapter on ulcerative inflammation; and much of the obscurity in which he left the subject remains. For a general consideration of the subject, it may suffice to speak (as I have done) of the removals of the particles of inflamed parts, which are not on an open or exposed surface, as the "interstitial absorptions" of inflamed parts. Then, the term "ulceration" may be employed to express the removals of the superficial or exposed particles of inflamed parts. If these superficial particles may be supposed to be absorbed, the process of removing them may be termed "ulcerative absorption;" but if it is more probable that their removal is effected entirely by ejecting them from the surface of the inflamed part, then the term "ulceration" may sufficiently express this ejection, and will stand in stronger contrast to the "interstitial absorption" of the particles that are not so ejected.

I have lately referred to the uncertainty whether, as the cavity of an abscess enlarges, the tissues that are removed from the inner surface of its boundary walls are absorbed, or are disintegrated and mingled with its fluid contents; in other words, whether they are absorbed or ejected. The same uncertainty exists in the case of ulceration. Is the enlargement of an ulcer effected by absorption of its boundaries, or by the gradual detachment and casting-off of particles from their free surface? Both methods of enlargement may, perhaps, in some cases, ensue; but the probabilities are in favour of the enlargement being, as a rule, effected by the ejection of particles.

Thus:—1. Parts to be removed from a surface are generally cast-off rather than absorbed, as cuticles of all kinds are, and the materials of secretions; so that, by analogy, we might assume that the particles

of the surface of a spreading ulcer would also be cast-off.

2. The materials of the ulcerating tissue may be sometimes found in the discharge from the ulcer. In most cases, indeed, this is impossible; but perhaps it is so only because, when the tissues are degenerate, and broken-up, or decomposed and dissolved, we have no tests by which to recognise them. In the case of bone, however, some of the constituents of which are not so easily disguised, the ejected materials may be found. In one of his lectures delivered in this theatre, Mr. Bransby Cooper mentioned that, while in pus from soft parts only traces of phosphate of lime were found, the pus from around diseased bone contained in solution nearly 2½ per cent.* A similar, but less complete observation, had been made by Mr. Thomas Taylor,† and by v. Bibra;‡ and we may be nearly sure that the phosphate of lime was, in these cases, some of what had existed in the diseased bone.

3. It strengthens this belief to observe, that, in many cases, small fragments of bone and other tissues are detached and cast-out with the fluid secreted from the ulcerating part. These, indeed, when they are not fragments of tissue detached by ulceration extending around them, are good examples of the transition that may be traced from ulceration to sloughing or gangrene of parts, between which, if ulceration be always accomplished by ejection, the only essential difference will be one of degree: the ulceration being a death and casting-off of invisible particles of a tissue, while gangrene implies the death and casting-off of visible portions.

4. And it may be proved of many that we call ulcers that they begin as sloughs which are cast off, and leave the ulcerated surface beneath. We may often see this, on a large scale, in the instances of what

* Medical Gazette, May, 1845.

† Stanley, on Diseases of the Bones, p. 69.

‡ Chemische Untersuchungen verschiedener Eiterarten, p. 85. It may seem that, in these cases, a further proof is needed that the quantity of bone-earth discharged with the pus is proportionate or equal to the quantity lost by the ulcerating bone. But this proof may be neither possible nor necessary; for if what has been already said, of the conformity of the properties of inflammatory and reparatory products with those of the tissues from which they are produced, be true, then will also pus from diseased bone possess more bone-earth than pus from any other tissue, even though the bone be not ulcerating. Granulations upon bone doubtless contain more bone-earth than those from soft parts, and they may ossify: now the relation of pus to granulations is commonly that of degenerating cells to the like cells developing; therefore we might expect that pus from bone, like granulations from bone, will contain a large proportion of bone-earth, independent of what may be derived from the ulceration of the bone.

are called sloughing ulcers; but Dr. Baly has proved it for a much wider range of cases, in his observations on dysentery, in which he has traced, how even the smallest and the most superficial ulcers of the intestine are preceded by the death and detachment of portions of the mucous membrane, with its covering of basement-membrane and epithelium.*

From these considerations, we may hold it as probable that ulceration is, usually, the result of the detachment of dead portions or molecules of a tissue, and that the substance removed in the process is not absorbed but ejected. There are, indeed, some cases which may make us unwilling to admit, at present, that all ulceration is by ejection; such as those of bone ulcerating under cartilage, or in the rapid extension of inflammation within it, or such as the spreading ulceration of the vertebrae, or the heads of bones, that is not attended with external discharge of fluid. These may interfere with the universality of the rule, but not with its generality.

But, if we may believe that the removal of a tissue by ulceration is generally effected by ejection of its substance, the question may be asked, in what form is it ejected? Dr. Baly's observations enable us to say that, in the first instance, a visible slough is detached, a portion of the tissue dying and being disconnected from the adjacent living tissue. But, after this is done, when an ulcer enlarges, or extends and spreads, is the material of the tissue still removed in visible sloughs or fragments? Certainly it is so sometimes; for we may find little fragments of bone in the discharge from ulcerating bone, especially in strumous ulceration. But in other cases we have no evidence of this kind; we cannot detect even microscopic fragments of tissues in the discharges, and we must suppose that they are removed, in a state of solution or of molecular subdivision, in the discharge from the diseased part.

To speak of the solution of tissues in the discharges of ulcers may seem like the revival of an old error long since disproved. But though the expression may be revived, it is with a new meaning. The proof has, truly, been long completed, that healthy tissues, even though they be dead, cannot be dissolved in pus, or any such discharge; but the tissues that bound or form the walls of a spreading ulcer are not healthy; they are inflamed, or otherwise diseased and degenerate; and they may now be soluble in fluids that could not dissolve them while they were sound. Insolubility is as great an obstacle to absorption as to ejection in

discharges; no tissue can be absorbed without being first so far changed as to be soluble in fluids with which it was before in contact and unharmed. Therefore, whether we hold the ordinary spreading of an ulcer to be by absorption of its boundaries, or ascribe it to their ejection, we must, in either case, admit that they are first made soluble. And if this be admitted, then it is most consistent with analogy, and most probable, that the extension of an ulcer, independently of sloughing, is accomplished by the gradual degeneration of the tissues that form its walls, and by their being either disintegrated and cast-off in minute molecular matter, or else dissolved and ejected in solution in the discharges from the ulcer.

The solution here spoken of is such as may be effected by the fluid discharged from any spreading ulcers; and we may doubt whether all discharges from ulcers possess a *corroding* property, such as Rokitsansky seems to ascribe to them, and such as he considers to be the chief cause of the extension of all ulcers. We may doubt, I say, whether all ulceration can be described as a corrosion or erosion of the tissues by ichor; but, on the other side, we cannot well doubt that the properties of the discharge from an ulcer, or a sloughing sore, may have a great influence in accelerating the degeneration and decomposition, and thereby the solution, of the tissues that form its walls or boundaries. Many ichorous discharges from ulcers inflame and excoriate the parts over which they flow; and one constituent of inflammation is the defective nutrition of the proper elements of the affected tissue. Many such discharges, also, are in an active state of decomposition; and their contact with the tissues cannot but have some tendency to excite decomposition in them; a tendency which the tissues will be the less able to resist, in the same proportion as they are already feebly maintaining themselves, or as they have been moved by inflammation from their normal conditions, and their normal tenacity of composition.

On the whole, then, we may conclude, respecting the process of ulceration, that its beginning is usually the detachment of a slough, or portion of dead tissue, by the removal of the layer of living tissue that bounded it; that the spreading of an ulcer, independent of such visible sloughing, is effected by the tissues that bound it becoming degenerate, and being detached in minute particles, or molecular matter, or being decomposed and dissolved in the fluid discharge or ichor; and that this spreading may be accelerated by the influence of the discharge itself, which may inflame

* Gulstonian Lectures. Medical Gazette, 1847.

the healthy tissues that it rests on, and may exercise a decomposing "catalytic" action on those that are inflamed already.

I have already said that the products of inflammation are commonly removed, in ulceration, together with the elements of the tissues in which they are deposited. And all that has been said of the changes that the tissues undergo previous to ejection or solution, may be said, also, of the products of the inflammation which commonly precedes and accompanies the ulcerative process.

I need hardly say that we have no knowledge by which to explain the peculiar and characteristic forms of certain ulcers. We seem wholly without a guide to such knowledge; but the existence of such specific forms is conclusive against the supposition that the extension of an ulcer is entirely due to corrosion by an exuded fluid. Such a fluid would act uniformly, unless the various effects of disease on the tissues bounding the ulcer should make them variously amenable to its influence.

The last enumerated effect produced by inflammation in the tissues in which it is seated is gangrene, mortification, or sloughing.

In the usual enumeration of the effects of inflammation, it is commonly implied that the processes of effusion of lymph, suppuration, ulceration, and mortification, may be taken as the expressions of so many successive degrees of severity of the morbid process. But this is far from being unconditionally true. The exciting cause of the inflammation, the tissue affected, the condition of the blood, the general amount of vital force, and the degrees in which the bloodvessels can adapt themselves to the transit of various quantities of blood; all these, and, perhaps, several other things, have as marked an influence as the severity of the disease has in determining the result of an inflammation to be gangrene of the affected part. It may be nearer the general truth, to say that the probability of gangrene ensuing in inflammation is proportionate to the sum of the intensity of the disease *plus* the debility or defective vitality of the affected part, whether that debility have a general or a local origin. But, indeed, in any case of gangrene that may be regarded as inflammatory, it is very hard to say what may be ascribed to the inflammatory process, and how that process affects the issue, so great are the number, and so diverse the natures, of the several morbid conditions that are from the first, or in succession, involved. Certainly, it is not possible to speak clearly of inflammatory

gangrene without constant reference to many other forms of local death which lie far beyond the range of these lectures. For this reason, and because a separate series of specimens in the Museum is devoted to the illustration of the death of parts, I shall here conclude the account of the phenomena and effects of inflammation.

ON THE NATURAL HISTORY AND CULTIVATION OF IPECACUANHA IN THE BRAZILS.
BY M. WEDELL.

THE *Cephalis Ipecacuanha* was discovered in 1824, in the province of Matto-Grasso, but its cultivation in this district was not commenced until the year 1832. The forests in which the plant grows are readily recognised. They abound in the basin of the Rio Paraguay and its tributaries. It does not thrive on the immediate banks of rivers, their periodical inundations being prejudicial to its growth. It flourishes best in a soil consisting of mixed sand and vegetable mould. The *Cephalis* attains to about the size of the *Daphne* of our own woods. It grows in clumps, which the gatherers, or *poayeros*, (so called from *pe-aya*, the Indian name for *Ipecacuanha*) call *redoleros*.

In collecting the root, the *poayero* seizes in one hand, if he can, all the stalks of each clump, and with the other hand digs them from the earth with a see-saw movement. The proper roots are then picked out. A labourer, in this way, collects from eleven to thirteen pounds a day; which, when dried by the heat of the sun, loses half its weight.

The propagation of the *Cephalis* is by seed, or more frequently from the suckers, which the *poayero* rejects from among the roots, as unfit for commercial purposes.—*L'Union Médicale.* x

*. M. Wedell is not very clear in his account of the early history of *Ipecacuanha*. He no doubt refers to its cultivation in a particular district, since we learn from that excellent authority, Pereira, that *Ipecacuanha* was used in Paris in 1686. The plant was brought from the Brazils in 1800. In 1802, it was described by Brotero under the name of *Callicocca Ipecacuanha*, and in 1818 it received from Richard the name of *Cephaelis Ipecacuanha*.

Original Communications.

OBSERVATIONS ON THE
CONDITION OF THE BODY AFTER
DEATH FROM CHOLERA.By WM. FREDERICK BARLOW, M.R.C.S.
Resident Medical Officer to the Westminster
Hospital.(Suggested by a Case communicated to the
Writer by THOS. GREEN, M.D. F.R.C.S.,
Surgeon to the Bristol Infirmary, &c.)

[Continued from p. 21.]

THE *long delay of rigor mortis* in the case which occurred at Bristol was certainly a very remarkable feature of it. Was it attributable, in any measure, to the warmth of the body being preserved so long? We must not be too ready to violently force *simultaneous* circumstances into the imaginary relation of cause and effect; and so commit an error which has led so often and obviously, elsewhere, to the spread of false knowledge and the discouragement of true. It happens frequently that rigor mortis lingers until the body cools; but it does not invariably happen. I have seen, as many others have done before, animals become rigid, perfectly rigid, whilst warmth remained. But there is an observation which would of itself suffice to prevent any one attributing the deferred rigidity, in the case in question, to the tardy cooling of the corpse. M. Ollivier (as Dr. Taylor has reminded us in his lectures on the signs of death), has found some bodies dead from cholera, *at once very warm and perfectly rigid*. More cases might be cited without trouble or research; but, as they are furnished not by *cholera*, they would, though perfectly applicable, seem less strikingly in point. It is very easy to conceive long retention of warmth, long maintenance of irritability, long retardation of rigor mortis, and long resistance to the changes whereupon putrefaction depends, occurring *together*; and this would seem to have been exemplified in the instance which was observed at Bristol.

There appears to be a marked disuniformity as to the time at which rigor mortis sets in after dissolution by

cholera,—a circumstance to be in part, if not *altogether*, explained, by the fact, that death surprises in this disease at a time when the muscular fibre is most differently situated as to its amount of irritability. It is known well enough that the phenomenon of rigidity is generally postponed until the contractibility of the fibre is either entirely or almost exhausted. And there is certainly no more cardinal feature of this form of muscular contraction, for I cannot but regard it as such, than the fact that, though its *power* and *duration* is as a rule proportionate to the amount of irritability at the time of death, its *occurrence* should be hindered until that property be completely or all but abolished.

When we consider that cholera attacks both the weak and the strong, that it respects no age, and that it happens sometimes in the course of maladies which have produced manifest, perhaps alarming prostration; that its duration varies not a little; that it is attended by cramps, which, to speak comparatively, are slight and partial, or universal and violent, and endure unto death;—we may safely conclude, without any further consideration, that very opposite states of muscular irritability must necessarily prevail at the moment of dissolution, and that the time at which rigor mortis will appear, the force it will be exerted with, and the period of its remaining, will all, as a consequence, be far from uniform.

The state of nutrition of the muscular tissue may be mentioned in reference to rigor mortis, not only as respects death by cholera, but other forms of it. Muscular, or, as they should be called, extraordinarily muscular persons, are of course most likely to exhibit the phenomenon in the most marked and lasting way. Atrophy, or that impaired amount of nutrition which would hardly be recognised as such, (and we do but observe this matter rudely), leads on the other hand to a less palpable and abiding form of it. The remark, as need scarcely be observed, applies equally to the involuntary as to the voluntary muscles—to the heart as to the biceps. Paralysis does not prevent rigor mortis, unless, as Sommer shows, it interferes with the nourishment of the muscles. This physiologist once remarked an entire absence of

rigidity on the paralysed side, the muscles whereof appear to have been in an unhealthy state.

Fatty degeneration, (which I speak of from its commonness), has no doubt a great influence on the degree and duration of rigor mortis.* It would too, I should think, if excessive, either lead to the prevention of cramps in life-time, or very much modify their power, for we cannot but suppose that *cateris paribus* the best nourished and most irritable muscles would be most liable to this peculiar form of spasmodic action. It is with the state of the living, (only in a larger, more emphatic sense) as with the condition of the dead. It is modified by many circumstances that we know, by more that we know not. How can we expect diseases to run their course in sameness, seeing that the subjects of them so manifoldly differ? How look for precisely the like states in death, perceiving clearly that at the time of dying there are many parts and actions of the body extremely differing in different persons?

Even the remedies given for the disease, may, if they have circulated, have more relation to the time of commencement of violence, and duration of rigor mortis, than might be at first supposed. I am led to the remark by the influence of chloroform, which not only, as may be shown by experiment, impairs the irritability of the muscles during life-time, but leads to unusually early rigor mortis. This I have seen myself.† It is well known that the exhibition of chloroform has diminished, and sometimes allayed, the cramps of cholera; and it may be presumed reasonably to have accomplished this by virtue of its power to lessen, or

annihilate, muscular contractility. And it is surely not extravagant to suppose that rigor mortis *might* set in somewhat earlier than common in certain cases where chloroform has been largely given, seeing that whatever impairs the irritability of muscles is favourable to their rapid post-mortem rigidity. Animals killed in the chase, being "tired to death," have been known to stiffen almost as soon as dead. Why so? Because their irritability was utterly, or almost utterly, spent. Had they been destroyed of a sudden, during sleep, there would have been just the opposite condition of the muscular fibre, and a state wherein the postponement of rigor mortis might have been properly looked for.

The degree of swiftness with which a man dies in cholera, and the circumstance of death happening in the cold stage or not, must, of course, be considered in reference to the question of rigor mortis; nor must the fact of dissolution being apparently hurried by sudden efforts on the part of the patient, be forgotten, for death, in such a case, may be supposed to leave the muscles more irritable than they would have been, had the disease been a more lengthened course, and more exhaustion taken place, from distress, sleeplessness, and other sources of prostration ere life was past. But with regard to cholera, as well as with reference to disease in general, the state of the muscular system after death is very apt to be most cursorily touched upon, and the pathologist fancies he has done enough if he note vaguely the circumstance of rigidity, without looking to the period at which it occurred, or sufficiently and fully connecting it with the condition of the body which prevailed in life-time. And yet the phenomenon, taking simply its universality into fair account, is full of interest, but that interest is unmeasurably added to, by the diversity it puts on in conformity with differences of the muscular system in various persons, and the great dissimilarity of their mode of dying. It is a chapter in the history of death, but it forms a portion also of the history of maladies; and it is certainly deserving of a far more general and comprehensive study than it has hitherto received.

Observations have been made upon the position of limbs rigid after death

* It would be of no little interest to examine this question thoroughly, in reference to the heart. What has been called concentric hypertrophy, by a grave pathological mistake, would, I should suppose, never be found where this degeneration is both general and extreme. I asked Dr. Quain to tell me his experience on this point. He says that hearts in such a state of degeneration are "generally found dilated, and their pariete. flabby," but that he has seen them "firmly contracted" where the degeneration was not extensive nor excessive.

† Dr. Tyler Smith says that he has seen it happen in the frog with a ten minutes of the heart ceasing to beat. See London Journal of Medicine, Dec. 1849. It would be important to determine accurately the time at which rigor mortis is wont to occur after death by chloroform in the human subject. Where death is suspected to have been caused by it, the knowledge of this matter *might* perhaps much help inquiry.

by cholera, which might lead to the idea that postures of distortion are *peculiar* to this disease; but this would be an erroneous notion, though it be far from improbable, looking to the nature of cholera, the rapidity of its progress, and the strange attitudes in which its victims perish, sometimes, that such postures are more commonly met with than in other affections. I was told by a nurse, whose task it was to lay out not a few who had died of cholera, that she was always careful to straighten the limbs very soon after the occurrence of death, because they were wont to stiffen very quickly, and she was then unable properly to 'compose' the corpse. M. Cruveilhier states that he has rarely seen those semi-flexed positions which some have delineated as proper to this disease; but this might have been owing, in part at least, to those whom he examined having died in a hospital where due care was taken to arrange the bodies in due form. This pathologist, however, gives a striking example of the disordered postures whereto he makes reference. It is related by him, that an extremely vigorous man, 25 years of age, died of cholera in *seven* hours, enduring cramps to the last. Twelve hours after death, the body was rigid, and there was flexion of the legs upon the thighs, and of the latter upon the pelvis. The conjunctivæ were dark, the body livid, the eyes shrunken, and the whole aspect singularly frightful. The question to be asked clearly is—was this body "laid out?" were the limbs straightened as usual? Another question is—did any muscular contractions occur after death, and so discompose and distort the corpse? Some trifling alteration in the position of the parts may occasionally be owing to rigor mortis, and I may refer to some observations of Sommer, which bear directly on this point, but I think any physiologist of judgment would pause very long before he attributed such an attitude as this to the effect of that phenomenon; and I should not imagine that Cruveilhier, who is silent upon the matter, would think of so explaining it. The knowledge which we have of post-mortem contractions affords a far better explanation of some changes of posture occurring after death than any which could be furnished by rigor mortis. But in reference to this topic, it is

indispensable to note most accurately the position at the moment of death, for, if left to itself, it will remain as it was. The common practice of "laying out" the dead, has, I need not say, reference to the acknowledged fact, that persons stiffen in the form they are left in. In various cases of violent death strange attitudes are found, well calculated to amaze the vulgar, and make yet deeper the horror of the scene. No one was present to arrange the body; the attitude of death remains. The drowned have been found in all kinds of postures. Lately I saw the arm retracted to the utmost, in a body stiffened firmly by rigor mortis. It was that of a paralytic, and had been so retracted before death. Rigor mortis may be held to fix positions rather than make them. At the moment of my writing this, there are two frogs before me; rigor mortis has occurred long since. In one, the limbs, disposed symmetrically, lie a little apart; the other rests in a somewhat grotesque attitude. They are, with the exception of a slight flexion of the toes of one of them, exactly as I placed them before rigor mortis was established.

For myself I have never seen a greater degree of rigor mortis after cholera, than I have noted after other affections that have run their course speedily. In strong and unusually muscular subjects who die of acute diseases, it is not singular to remark the extreme firmness wherewith the limbs are stiffened, and the clear outline of many of the superficial muscles.

The involuntary muscles have sometimes been found remarkably contracted after death by cholera. The heart, the bladder, and the intestines, have all been discovered, though anything but invariably, in a marked condition of rigor mortis.

Whether or not the involuntary muscles are, to speak *generally*, most contracted (where they are so), in those cases in which rigor mortis is specially evident in such as are voluntary, I cannot say, but it is most likely that both sets of muscles would be discovered, in some instances, similarly affected to an extreme degree.

The heart has been often seen very rigid, but the rigidity of this muscle is far from universal, and in not a few instances it is quite flaccid.

The bladder has been very commonly

found in extreme contraction. One writer has likened it to the unimpregnated uterus, on remarking it in this condition, from the thickness of its walls and the smallness of its cavity.

The intestinal tube has presented more or less general marks of rigor.

In the "Madras Reports" it is stated that the intestine was sometimes, but rarely, contracted; one case is mentioned in which the arch of the colon was in a state of rigor, and another, in which there were several contractions of the same part.

There are some examples to be found in the "Bombay Reports."

In one case there was a contraction of the colon from the cæcum to the sigmoid flexure, so that the sides of the intestine were brought into close contact, and it felt thick and solid; the part so influenced was not larger than the middle finger. In a second case, the colon is reported to have been "nearly obliterated," in consequence of contraction. In a third, the transverse arch of the same portion of the canal is spoken of as "almost impervious."

The Cholera Gazette for 1832, also contains facts of the like nature.

In a case examined by Mr. Pilcher, about twelve inches of ilium were found contracted; and instances are given of partial contraction of the colon.

In a post-mortem examination, made in the presence of Dr. Sims, Dr. Hope, Mr. Mayo, and Mr. Perry, the stomach was found "contracted."

Dr. Kirkes has kindly informed me of a case which occurred during the late epidemic, wherein, 15 hours after death, "the heart was pretty firmly contracted; the urinary bladder, and large intestines, were contracted also. The limbs were exceedingly rigid, and the muscles in the most extreme degree of contraction."

But no form of rigor mortis of the involuntary muscles is *peculiar* to cholera. Rigidity of the heart is no uncommon circumstance, as every one knows; and I have seen lately some well-marked cases of it in various affections.

It was probably partial rigor of the intestines that was referred to by Harvey, famous for his great discovery, in his "Anatomical Examination of Thomas Parr," a man remembered for having lived long. "The small intestines pre-

sented several constrictions, like rings, and were muscular."*

The following observations on rigor mortis of the involuntary muscles, to be found in the "Supplement to the Second Volume of Professor Müller's Elements of Physiology,"† may not be inappositely cited here. "The rigidity of voluntary muscles, from being the most evident, has attracted most attention, and the phenomenon has, until lately, been described solely in relation to this class of muscles; but sufficient evidence has now been accumulated to warrant the conclusion, that the involuntary muscles also are affected by a post-mortem rigidity, which is, in all essential respects, comparable with that seated in the voluntary muscles. And this is true, not merely in regard to those involuntary muscles which, such as the blood and lymphatic hearts, are constructed of striped fibres, but also with regard to the tissues composed of unstriped fibres, such as the contractile coat of blood-vessels, and of the large excretory ducts. The observations of Dr. George Budd and Mr. Paget have proved this in the case of the heart; and the occurrence of rigidity in the digestive canal has been shown by Valentin, who found that if a graduated tube be connected with a portion of intestine taken from a recently slain animal, filled with water and tied at the opposite end, the water will in a few hours rise to a considerable height in the tube, owing to the contraction of the intestinal walls. The contraction of the blood vessels after death was observed by John Hunter, and is now regarded as a well-established fact, and one by which the empty state of the arterial system after death is in a great measure explained."

In considering the *duration* of rigidity, be it in reference to cholera or not, regard must always be had to *temperature*. It is related by Nysten that Laennec shewed him a squirrel which in a cold season was rigid seven days after death.

In a paper, which I wrote, not long ago, on the muscular contractions which occasionally happen after death from cholera, I observed that in one respect (if not in more than one) they may be

* See Works of W. Harvey, M.D., Edition of the Sydenham Society, v. 596.

† By William Babt, M.D., F.R.S., and William Seabrook Kirkes, M.D.

likened to the effects of rigor mortis which, as may sometimes be observed of these contractions, affects parts in *succession*. This remark is far too general, and may be thought to imply more than I intended. Rigor mortis and the movements in question, have, as will be apparent to every body, many and extreme points of difference. Rigor mortis does not ensue until the irritability of the muscle is entirely or almost exhausted; but these movements are signs of irritability, sometimes of a great degree of it, are, in some cases at least, to be *excited*, whereas nothing can excite this form of rigidity, but its one common cause. Rigor mortis influences both sides of the body equally, producing effects not less symmetrical than the disposition of the muscles themselves, and repeats itself in various subjects, making an allowance for occasional differences, with a striking sameness; but these contractions are diversified as to form and power, affect different muscles in different subjects, cease and return repeatedly; whereas the contraction of rigor mortis being once over, is never renewed. But why proceed further?

The more we contemplate the rigidity of death, the more remarkable does its individuality appear. No other form of muscular contraction can properly be compared with it; no other so comes, so progresses, so endures, so departs. Yet such rigidity, though it be caused by a special action, which is in nowise to be explained as other kinds of action are, is quite within the pale of the admitted law, that the force of an action, no matter what its nature, is in dependence on the condition of the part performing it. Nor can it be necessary to enforce the observation by repeating at length what has been said already, as to the relation between the power and endurance of rigidity and the perfect nutrition of the muscular fibre.

Two points yet remain to be considered in reference to the case which occurred at Bristol; one relates to the retardation of putrefaction which was observed. This doubtless considerably added to the doubts of the relatives of the deceased. Putrefaction is, of course, always watched for with intense anxiety by those who are unassured as to the reality of death. Five days, in this case, passed away ere putrefaction showed itself. The time was long, notwithstanding death by an affection wherein

this process tarries. But instances might be cited of its far more protracted appearance, though actual death had happened—not death-trance, a name used sometimes most improperly where dissolution was absolute, because things had happened not to take their accustomed course in the interval between the cessation of the respiration and the beginning of decay. A case occurred at Deptford, in 1844, in which a body, dead in reality, was supposed by some to be in a death-trance. It was watched long, and opinion varied as to its true condition. Putrefaction had not “far advanced” when so many as thirty-five days had elapsed after dissolution. The deceased was *young*, and had died *suddenly*. In the case at Bristol the circumstances were such as to make the late putrefaction no such very especial matter for surprise. The death happened in a *young* subject, was accomplished with *celerity*, and effected by a disease wherein the dead are slow to putrefy. The temperature was not high, and fresh currents of cool air were from time to time admitted into the room the body lay in. We must not construct marvels, nor magnify everything which may somewhat deviate from the course of things.

Let me here add one word further on the relation of putrefaction to the temperature of the dead. Prolonged heat and extremely tardy putrefaction have been observed *together*: but has the body been seen at the *same time* quick to putrefy and slow to cool? Dr. Taylor not long ago published in the *MEDICAL GAZETTE* an instructive “Case of Rapid Decomposition of the Human Body.” I inquired of him how quickly it parted with its warmth, and he replied:—“Unfortunately no trustworthy history could be obtained of the cooling of the body, as it was in the hands of the nurse during the night and early part of the morning. It was quite cool when I saw it *seventeen* hours after death.” It is observed by M. Deschamps, that “so long as the body preserves its natural heat there is no discoloration of the abdomen.”* It is to be observed of the case for which I am indebted to Dr. Green, that the loss of heat, the occurrence of rigidity, and the

* He remarks, also, that the discoloration in question is very often coincident with cadaverous rigidity.

abdominal putrefaction, were nearly *coincident* marks of phenomena.

Dr. Taylor has been good enough to send me the following note of some experiments which he has been performing in reference to the question of animal putrefaction producing heat:—"I have tried experiments by inserting delicate thermometers in the midst of putrefying animal matter, but have not found the least change of temperature during the process, although the viscera were kept in glass vessels covered."* There was a thermometer outside for comparison.

It need scarcely be added, that the tendency to putrefaction is much greater after some diseases than others. The remark holds good of affections which agree in leaving their principal traces in the same region. In cholera, as we have seen, it is later than common; but in child-bed fever it is often, as Dr. Kirkland and others have noticed, quick to appear. The same may be said of ordinary enteritis. Mr. Phillips observes of a case of intestinal obstruction:—"Although the death occurred only thirty-four hours before the examination was made, and although only sixty hours before he was apparently in good health, decomposition was greatly advanced.

"The abdomen was enormously distended; the scrotum was as large as a child's head; the surface of the trunk was covered by very large vesicles containing a dark-coloured and very offensive fluid; and a good deal of dark bloody fluid had escaped from the mouth and nose. The cellular tissue was so distended with gas, that as soon as an excision was made through the skin it escaped with a loud hissing noise."†

The aspect of the countenance in the Bristol case was described as placid, like that of one asleep. It probably would have excited less attention had it not been associated with retained warmth, deferred putrefaction, and delayed rigidity. It was certainly, considering the mode of death, an unusual aspect; for cholera leaves, generally, rude and deep marks of its swift, desolating course. The dead look much as the dying: there is death in the visage

some time ere it comes, and the features at the moment of the last expiration seem hardly to undergo the shadow of a change. How different when some face, crimson with health perchance, turns deadly pale from sudden, fatal hæmorrhage, the blood flying from the cheeks scarcely more swiftly than life from the body!*

It must not be thought that the countenance has *always* a striking haggardness after death by cholera. Not only was there none in the example before us, but Cruveilhier mentions an instance in which a person who died of this disease might have been supposed to have perished from some other malady. But, generally speaking, the eyes are unusually sunken, and there is a peculiarly shrunk and ghastly countenance. Even the faces of children manifest it, though in them there is so frequently observed, after other maladies, and before the time of rigidity, a most serene, nay, to some a momentarily delusive, physiognomy.

A change has been seen in the colour of the face, which becomes less livid, but *gradually always*, as I should suppose. It sometimes puts on quite a red tint, which, like the less conspicuous change, is doubtless owing to alterations in the blood of the superficial vessels. As to the general hue, it varies much: in a case recorded by Cruveilhier the superior extremities were so livid that they at first sight seemed gangrenous to a medical observer; but in some instances the lividity is infinitely fainter, and might pass without any particular remarks.

Let us, before concluding, pass in short review some of the principal points which have been noticed by observers as to the state of bodies dead from cholera.

I. The aspect has been unusually cadaverous, though scarcely more so, in many cases, than it was in life-time, for the disease has power to make all physiognomies subordinate to its own: but the features have more than once

* A beautiful allusion, as some readers will remember, is made to the remarkable paleness which overspreads the features when death is owing to a sudden loss of blood, at the end of the tenth book of the *Æneid*. The following lines are from the touching description of the death of Lausus:—

"At verò nit vultum vidit morientis et ora,
Ora modis Anchisiades pallentia miris:
Ingemuit miserans graviter, dextramque
tetendit."

* Temp. 55° to 57°.

† In this case a portion of the ilium was strangulated, another part of the intestine looked gangrenous, and there was some dark fluid blood in the abdomen. See *Medico-Chirurgical Transactions*.

been observed in a different state, in nowise talling of the cause of mortality.

II. The whole body has looked extremely shrunken; the hands have been very shrivelled; the distinction between the ages of corpses has not been nearly so easy as in general.

III. The colour has been dusky, often remarkably livid, and has been noticed to become lighter, and even to redden; but the hue, not changing equally, has sometimes presented a peculiar mottled appearance.

IV. Rigor mortis has set in, occasionally, with an unusual hurry; it has also been deferred extraordinarily late; has occurred when the limbs have been more or less flexed, and so fixed them; has been seen in every degree; has been noticed to influence the involuntary muscles, the bladder very frequently, the heart not rarely, the intestines occasionally. It has presented all those varieties which might have been anticipated, seeing that the victims of the disease have been furnished by persons of every age, strength, and condition.

V. Contractions have taken place in the voluntary muscles, and been excited by percussion: they have been partial, weak, transient, or more general, stronger and long-enduring; they have varied considerably as to time of occurrence, progress, appearance, and effect, and have, for the most part, been observed in males, the most marked instances having been furnished by very muscular subjects who perished rapidly.

VI. The case which occurred at Bristol exemplifies, amongst other things, an unusually long maintenance of temperature; and there seems no doubt of many examples having happened in which the heat of the body rose considerably after death.

VII. Putrefaction was generally more delayed than usual, and has been noticed to be especially tardy. I believe it may be stated that none of the foregoing points are, strictly speaking, *peculiar* to cholera; though there was much that was indicative of the nature of the affection in the general appearance, whereof words, after all, can but give an imperfect history. The lividity, the change of colour, the varieties of rigor mortis, the lingering temperature, the rise of the same, and the muscular contractions, have all been observed in other cases than those of cholera.

I confess, when I began the considera-

tion of the subject, that there was much in the condition of the body after cholera which, in my eyes, stood by itself. I speak not, of course, of the state of the intestines,—of what may be termed the morbid anatomy of the affection, in a peculiar sense, but of the phenomena which may be observed in the skin and muscles, the state of the temperature, and the event of contractions. But it must be admitted that we know next to nothing, from observations made at home, as to these two questions, if we except what cholera has taught us; and we cannot too moderately estimate such information as we have gained therefrom. The inquiry into the whole state of the dead, not in cholera alone, but other maladies, between the last respiration and incipient putrefaction, is in absolute infancy.* It needs and invites labourers. It would prove not of interest merely, but of *use*. It is called for by physiology, and especially demanded by forensic medicine; nor can medicine in general afford to forego it, since the *history* of some diseases cannot be truly called complete without it. Of course, many will ask *cui bono*—words heard commonly even in this advanced age.

As with the phenomena of cholera during life, so with others which may be witnessed after dissolution,—unless they be viewed *comparatively*, there is no chance, no hope, of appreciating them aright. We view subjects narrowly, and therefore obscurely, at first sight: not until we dwell upon them patiently, thoughtfully, do they reveal their features, and show forth their analogies. It is plain, even from the foregoing, that we ought to be well familiar with the diverse states of the body after death. In ignorance thereof we have no chance of checking absurd terrors, and of giving sound and reputable evidence on some matters of legal investigation. Novelties are ever exciting, ever popular, and such as relate to the dead, inasmuch as they more or less touch all of us, are ever likely to remain so, in a peculiar sense. Exceptional conditions will be sure to strike every one. Everybody will speculate on muscular contractions, talk of rise of temperature, and retarded putrefaction: a few will be apt to converse of “death

* I may here refer the reader to some of the questions discussed by Dr. Davy in his ingenious researches.

trances," and to suggest, on the strength of the wildest rumours, the holding of inquests. But why this occasional, ill-founded amazement? Is it, seeing the unutterable complexities of life, at all likely that the last breath should always leave the body in the same state? Perhaps we ought more to wonder than now we do that the condition of corpses is, on the whole, so uniform. I say not that this thought will weigh anything with those who have never spent ten minutes in reflecting upon life, but yet presume to speak of the vital functions as if it were the very easiest of all matters to understand them in health, and right them in disease. They expect a specific for every malady, as a matter of course; and, instead of being thankful for what medicine has accomplished, they are full of disappointment that it has done no more. How can they, who are ignorant of the phenomena of the living, judge truly of the condition of the dead? Is not the study of life the only means whereby the nature of death can be comprehended? Amongst the things least to be feared in this country, premature burial may be named. There were rumours afloat during the past epidemic which might seem to imply some danger of it; but where was there a solitary instance which could bear inquiry? We hear of marvels in the *distance*, and begin to puzzle ourselves; but everything would be different if we were *near*. The phenomena of the case at Bristol were not the same to the medical attendants of the deceased as they were to those who knew them by report alone. I could not help observing, when the cholera was raging, that it was more dreadful to some persons to read about than to others to see. They who were in the midst of it, trying to give help, were less full of dread and discomfort than many who were safely breathing, in pleasant places, the purest air. They had no time, at any rate, for needless terrors,—no time to sit shivering at mere fictions. There are some remarks in De Foe's "History of the Plague" which apply well to persons who take fright at nothing. Speaking of some strange rumours, he says: "But these stories had two marks of suspicion that always attended them, which caused me always to slight them, and look upon them as mere stories that people continually frightened one another with. First, that wherever it

was that we heard it, they always placed the scene at the farther end of the town, opposite, or most remote from where you were to hear it: if you heard it at Whitechapel, it had happened at St. Giles's, or at Westminster, or Holborn, or that end of the town; if you heard of it at that end of the town, then it was done in Whitechapel, or the Minories, or about Cripplegate parish: if you heard of it in the City, why then it happened in Southwark; and if you heard of it in Southwark, then it was done in the City, and the like." Inquiry should ever precede belief; but it is a pretty general habit to make belief precede inquiry, and so all sorts of delusions are cherished and abound. Mystery has innumerable worshippers. Would that truth had so many! Men will wander in the world of shadows: there abuse they and exhaust their energies. But students of Nature must be severe historians, not tellers of dreams; their object is not to mystify, but to make clear—not to invent, but to discover; and they may be naturally inclined to observe—"And surely you will easily believe that we, that have so many things truly natural, which induce admiration, could in a world of particulars deceive the senses, if we would disguise those things, and labour to make them more miraculous. But we do hate all impostures and lies, inasmuch as we have severely forbidden it to all our fellows, under pain of ignominy and fines, that they do not show any natural work or thing adorned or swelling, but only pure, as it is, and without all affectation of strangeness."*

STATISTICS OF UTERINE DISEASE.

M. HUGUIER gives the following statistics of 2527 patients under his care:—131 suffered from uterine congestion. Of these 8 had congestion of the body and neck of the uterus; 13 congestion of the body alone; 106 of the neck alone; and in 4 it was not determined which was the seat of disease.

According to the tissue affected, M. Huguier classifies these cases as 1, complex; 2, fungoid; 3, cedematous; 4, varicose. As influenced by causes—1, essential; 2, syphilitic, 3, dartreux; 4, diphtheritic.—*L'Union Médicale.* X

TWO CASES OF
FATAL OBSTRUCTION OF THE
INTESTINAL CANAL, BY PE-
RITONEAL BANDS.

(Read before the Abernethian Society, on
Thursday, February 14th.

By C. R. THOMPSON,
Late Honorary Secretary to the Society.

MECHANICAL occlusion of some part of the intestinal canal, by intra-abdominal causes, has lately attracted great attention among English surgeons; chiefly with regard to the propriety of performing gastrotomy, in the hope of finding and relieving the stricture.

Before any just conclusions can be arrived at on this point, more extended experience seems necessary, especially to determine whether we can predict with certainty the seat or nature of the constriction, during life: and whether the constriction is generally of such a nature that it might be relieved by an operation. This experience is only to be gained by the careful record of cases; and the exact report of the post-mortem appearances in such as terminate fatally. With this view, the two following cases, which have lately occurred in St. Bartholomew's Hospital, are offered to the Society.

The first is extracted from the registry of cases occurring in the Hospital, where it is reported by Mr. H. S. Webb; and the post-mortem appearances by Dr. W. S. Kirkes.

Case I.—Mary G——; a tall, dark-complexioned woman, aged 20, was admitted into Faith ward, November 13th, 1848.

Present condition.—Face dusky; eyes sunken, with livid areolæ around them; skin warm and dry; pulse 120, small, and rather sharp; lips dry; gums rather vascular; slight sordes about the teeth; tongue moist, coated on dorsum with very thick brown fur; clean at the edges. Bowels have not been open for seven days. Urine is said to be scanty, high-coloured, and depositing a thick sediment. Catamenia regular.

Complains of slight vertigo, and of nausea when she lies on the back. The abdomen is distended; generally dull on percussion; intolerant of pressure, especially in the umbilical region.

History.—Is a single woman, in domestic service; has always had good health until rather more than a fortnight ago, when she got wet feet, which checked the catamenial discharge. The next day she became very sick, and vomited whatever food she took, complaining also of a very severe gripping pain in the umbilical region. She suffered rigors, followed by great heat of the skin. She kept about the house for four days, although unable to attend to more than a part of her usual duties. Two days after the seizure she was seen by a chemist, who gave her some medicine, which was vomited. She was seen frequently by this chemist, but always vomited the medicine, as well as any food she took. Ten days ago she left her place, and saw a medical man, who gave her medicine which relieved her symptoms, and she got better, until a week ago, when she went out walking. On her return she went to bed, and during the night the pain in the abdomen and vomiting came on again, and with greater severity than before. She was bled, and has had leeches and fomentations applied to the abdomen during the past week, with the effect of relieving the pain. She has taken frequently aperient medicines, and enemata have been administered seven or eight times, without the desired effect.

Ordered.—Venesection to 12 oz. A dozen of leeches to the abdomen, to be followed by a poultice; a soap injection *per rectum*; to take calomel powder, ten grains, directly; and effervescing draughts, with one drachm of sulphate of magnesia, every sixth hour.

14th.—The bleeding was well borne; the blood not buffed; the pain seemed much relieved by the leeches; the powder was retained on the stomach; two soap clysters brought away no fecal matter. She passed a very restless, sleepless night; has vomited frequently a fluid of light yellow colour, and stercoraceous character; the expression is very anxious; features more sunken. Pulse 120, softer than yesterday. Abdomen very tense, and intolerant of pressure. Does not complain of actual pain, but of general discomfort.

Ordered.—Continue draughts; take of calomel three grains every sixth hour; repeat enemata; fomentations to abdomen.

15th.—Symptoms continue the same;

all nourishment given by the mouth is quickly returned; stercoraceous vomiting is unabated; complains of a sensation "as if something alive were moving" in her abdomen. The abdomen appears more distended, and particularly prominent to the left of the umbilicus; generally dull on percussion.

Ordered.—Continue draughts, with ten drops of laudanum added to each; continue pills. Brandy, two oz. Beef-tea, two pints, for two injections.

16th.—The first beef-tea enema was quickly returned, and followed in four hours by about a pint of dark bilious-looking fluid, containing abundant sediment of faecal odour and appearance: the second enema was returned unchanged. The vomiting and extreme restlessness continue. Tongue begins to dry. Pulse frequent, small, and jerking. Abdomen slightly resonant on percussion laterally; firm pressure on the abdomen causes nausea, but no pain. Takes arrow-root and brandy willingly.

Ordered.—Continue medicines.

17th.—She remains in the same condition; complaining more of abdominal pain. Continue medicines.

18th.—She is delirious and very restless; face very dusky and flushed; pupils contracted; skin hot and dry; pulse 124, small, and very feeble; vomiting of feculent matter continues; the enemata have brought away nothing; the abdomen is more tense, and intolerant of pressure.

She continued in this state until the evening, when she sank rapidly, and died at 7 P.M.

Post-mortem appearances 65 hours after death.—Limbs still slightly rigid; abdominal parietes discoloured from decomposition.

Brain not examined.

Lungs, with the exception of some emphysema, healthy. About half an ounce of clear fluid in the pericardium. Heart rather large; left ventricle contracted; not examined internally.

Peritoneum generally rather vascular; about four ounces of slightly turbid fluid containing flakes of lymph in the sac; some deposits of puriform matter at the bottom of the pelvis. Small intestine greatly distended; the peritoneal coat vascular and thickened; a broad line of redness ran along the border of the intestine where the coils lay in contact

with each other; a few slight shreds of lymph, here and there, held the coils slightly together at their surfaces of contact. Large intestine pale, contracted, and nearly empty. The transverse portion of the colon drawn down with the *right iliac region*, by a short narrow band proceeding from its lower border, and attached to the spine by means of the portion of mesentery corresponding to the last part of the small intestine. This band passed in front of the small intestine about an inch before its termination in the cæcum, compressing it against the spine, and constricting it so as to render it impervious. The portion of the colon from which the band originated was closely and rather firmly adherent to the constricted part of the small intestine, the thinner and more friable bands passing from one intestine to the other. The mesentery immediately surrounding the constricted part was inflamed, thickened, and matted around the intestine.

The entire length of the small intestine, as far as the constriction, was filled with liquid bilious matter, such as had been vomited during life. The mucous membrane was reddened and swollen in the neighbourhood of most of Peyer's patches, the individual glandulæ of which had burst, leaving spaces surrounded by a thickened border of mucous membrane. Each Peyer's patch thus presented a broad oval surface, the mucous membrane of which appeared worm-eaten, and as if irregularly removed by ulceration.

Here and there a swollen red solitary gland was seen. As the small intestine approached the seat of constriction, it became very vascular, and presented discoloured streaks and spots, as if from commencing sloughs. The piece of small intestine between the constriction and the cæcum was pale and contracted, and its mucous membrane irregularly ulcerated. Stomach distended with liquid bilious contents. Liver natural; gall-bladder distended with a quantity of thin dark bile; spleen natural; no morbid appearance of uterus or ovaries; kidneys large, heavy, and congested, but apparently of healthy structure.

CASE II.—Hannah R—, æt. 23, was admitted into Lucas ward, in the morning of February 7th, 1850.

Present condition.—Face very dusky and flushed; eyes dull, sunken, and surrounded by dark livid areolæ; skin

cold, moist, and clammy; pulse 140-50, very small and thready, at times barely perceptible; lips dry and fissured; tongue dry, coated with thick dirty white fur; bowels last open four days ago, but scantily; respiration natural, about 25.

She complains of pain from the most gentle pressure on any part of the abdomen, but especially in the hypogastric and iliac regions; the abdomen does not appear distended, and is generally soft, except about the umbilical region, where it is rather tense; there exists tympanitic resonance on percussion over the course of the colon, and in the epigastrium, but marked dulness in the umbilical and hypogastric regions. The patient is very restless; appears to lie indifferently on the back or either side, keeping the knees slightly drawn up. Complains of pain about the hypogastrium, and of constant nausea; vomits occasionally a light-coloured frothy fluid, having an appearance like working yeast, and of a decidedly feculent odour.

History.—She is a delicate married woman, a toy-painter by trade, which occupation she has pursued for years. Has been confined four times, and has two living children. The last labour occurred about five months ago, and was premature, at the seventh month of utero-gestation. Since that time she has never been perfectly well, suffering frequently from troublesome constipation, for which she has been under medical care; during the last three months particularly, the bowels have been generally costive, and she says the motions have been of unusually small calibre. The bowels were last open, after a constipation of three days' duration, on Sunday—i. e., four days ago, and then but very imperfectly. On Monday she complained of great pain in the abdomen, and stercoraceous vomiting commenced, as was learnt by a communication from her medical attendant. Since that day she has taken various aperient medicines; but the constipation, stercoraceous vomiting, and abdominal pain, continue unabated. Several enemata have been administered, and returned unchanged. The patient says she passed urine last night: catamenia regular.

A catheter was passed into the bladder, and about two ounces of thick, high-coloured urine drawn off. An elastic tube was introduced for some eight or ten inches by the rectum, and copious

enemata administered. It was determined in consultation that no operative proceeding was justifiable; and the patient was ordered wine, brandy, and beef-tea *ad libitum*, and to have large enemata.

Feb. 8th, 1 P.M.—She appears almost comatose, and fast dying; since 11 P.M. last night, she has taken four half-drachm doses of laudanum, to quiet the pain and restlessness, and has swallowed brandy and wine pretty freely; has vomited occasionally; abdomen more full, but soft; enemata came away unchanged: died at 4 P.M.

Post mortem appearances about 20 hours after death.

Thorax.—Heart and pericardium healthy; pleurae free from adhesion. Left lung healthy; infiltrated posteriorly with some bloody serum, but crepitant throughout, and floating in water. Right lung had lost its natural contractility, and presented a good example of extreme emphysema throughout its whole substance.

Abdomen.—On exposing the peritoneal cavity an extremely fetid odour was perceptible. The parietal layer of peritoneum was dotted with numerous small circular milk-white spots, more distinctly seen after exposure to the air; these spots were in the substance of the serous membrane, and not removable except by carefully dissecting it from the subjacent cellular tissue.

The great omentum was gorged with dark blood, and looked, at its lower part, like a bag of large distended veins. On raising it, it was found to be adherent to the subjacent intestines by recent lymph; on separating these adhesions carefully, there appeared an aperture in a mesenteric vessel of considerable size, freely giving exit to blood, of which about half a pint had escaped into the pelvis, probably during life. The contiguous surfaces of the intestines, both large and small, were also agglutinated together, and to the parietes of the abdomen, by recent lymph, which was easily broken down by the handle of a knife.

The greater part of the small intestine was of a deep red colour, very much distended in the upper part, and contracted below; about two feet of its length appeared more distended, and of a darker colour, than the rest of the intestine, almost black, or dark claret-

coloured: in the middle of this dark part was an ash-coloured slough, about three inches long, with well defined margin: the extremities of this congested fold of intestine were tightly girt by a firm band passing from the surface of another portion of intestine of the mesentery at the point of constriction: this band was very strong, and firmly attached at both its extremities.

The contents of the strangulated portion of intestine gave to the finger the sensation of hardened faecal matter, which was found to be caused, however, by the congestion and enlargement of the *valvulae conniventes*; for, on opening the canal, it contained only about one pint of dark fluid blood: the mucous membrane presented even a darker aspect than the exterior, and the internal surface of the ash-coloured spot was scarcely to be distinguished from the adjacent membrane: the mucous membrane was easily stripped off in various points. A considerable quantity of blood was also contained in the intestine, for a short distance above and below the stricture. The seat of constriction corresponded nearly to the umbilicus; but the coil of included intestine reached to the right lumbar region. It was a part of the lower end of the jejunum. Stomach healthy; also the large intestine, which contained near the caecal valve a few hardened scybala.

Pancreas and spleen of normal size and aspect.

Liver showed some portal venous congestion: otherwise healthy.

Kidneys rather large, but apparently normal.

These cases tend to confirm Rokitsky's opinion, that internal constrictions of the intestine are more frequent in females than in males; which, indeed, we should anticipate, on account of the great changes of position to which the abdominal viscera are subject in the former sex, in pregnancy, ovarian tumors, &c.

The same author has found abnormal peritoneal bands, or rents in the mesentery, to be the most frequent cause of internal incarceration. These bands are probably in most instances the result of some previous inflammation of the peritoneum; in many recorded cases we find a distinct history of mesenteric mischief; in the case related by Mr. Hilton, in *Med. Chir. Transactions*, vol. xxx., the patient, 20 years of age, was

the subject of mesenteric disease in early childhood, and, some time subsequently, suffered from symptoms which indicated peritonitis; here, from the history, the nature of the obstruction was accurately diagnosed, and found after death to be a band of false membrane, including a knuckle of the ileum. Mr. Druitt also records an instance where a boy, eleven years old, died after the operation of gastrotomy for the relief of the intestinal stricture; and old adhesions were found in the peritoneal sac, one of which was the cause of the constriction: the boy was stated to have suffered for eight years with occasional severe attacks of pain in the abdomen, subsiding under the use of medicine.

In the two cases which I have related, there was no evidence of former peritoneal mischief; indeed, from patients of this class it is always difficult to get a clear account of their ailments: it is curious that in both instances it was carefully observed that the abnormal band forming the constriction was the only one discovered of any strength or consistence, which seems to disprove the inflammatory origin of the bands, and raise a suspicion of their being congenital. Rokitsky mentions the frequent congenital occurrence of unusual length of the duplicatures of the peritoneum, or of supernumerary folds and pouches of that membrane; these pouches are chiefly found, he says, in the hypogastric, and more especially in the iliac and inguinal regions, and about the fundus vesicae; and communicate with the peritoneal cavity by a well-defined fissure or ring, which is frequently surrounded by a tendinous band, lying in the duplicature.

ON THE CONSTITUENTS OF RHUBARB.

M. GAROT gives the following as the results of his researches on the composition of rhubarb:—

1. That by treating rhubarb with nitric acid a peculiar acid is obtained, in the proportion of 8 to 10 per cent. in indigenous, and 15 to 20 per cent. in foreign rhubarb.

2. To this acid he gives the name of *erythroce*: it is soluble in alcohol and ether.

3. It combines with alkalies, and forms compounds which may be employed in the arts and in pharmacy.

4. The colouring property is greater in foreign than in indigenous rhubarb. — *Journal de Chimie Médicale*.

ON THE
OCCURRENCE OF A MUCO-PURU-
LENT DISCHARGE FROM THE
VAGINA IN SCARLATINA,
AND THE IMPORTANCE OF THIS SYMPTOM
IN RELATION TO FORENSIC
MEDICINE.

By ROBERT BARNES, M.D. LOND.
Lecturer on Obstetrics, Obstetric Surgeon to
the Western General Dispensary.

In the summer of 1843 I witnessed, in the wards of M. Chomel at the Hôtel Dieu, a case of scarlatina in a girl about 16 years of age. Owing to an unfortunate accident, by which I lost the greater part of the notes I made in the Paris hospitals, I cannot give a detailed account of this patient. She presented one symptom which, on account of its novelty, and its important relations to forensic medicine, I think is particularly interesting. After the decline of the eruptive stage, and when apparently convalescent, there occurred a muco-purulent discharge from the vagina, similar in character to the discharge which not uncommonly flows from the nares as one of the sequelæ of scarlatina.

There was evidence to show that this discharge did not exist at the time of the girl's admission, and that it was first observed at the period I have mentioned,—viz., after the decline of the eruption, when she had been some days in the hospital.

I believe that the discharge was not blennorrhagic, but a newly-observed feature in the pathology of scarlatina.

It is in the suspicion of blennorrhagia that lies the interest of this symptom in relation to forensic medicine. In this case, for example, an unmerited stigma might attach to the girl's character were it not admitted that the discharge might be the result of scarlatinal vaginitis. Numerous other charges of a grave nature might be founded upon such an appearance. Accusations of rape even might receive corroborative proof from its presence. About two years ago I saw a child of eleven years old who was recovering from scarlatina. It was then observed for the first time that she had a discharge from the vagina, and suspicions were immediately excited that she had been abused by a lad in the neighbourhood. This discharge might have been a

sequela of scarlatina. I believe it was.

The importance, then, of determining the possibility of a muco-purulent discharge as a consequence of scarlatinal vaginitis, is obvious. I am not acquainted with any author who notices this symptom. Dr. Tweedie has informed me that his attention has never been directed to such an occurrence, and that when a purulent discharge from the vagina has been noticed in scarlatinal patients he has concluded it to be blennorrhagic.

My colleague, Dr. Miller, whose elaborate work on scarlatina has thrown so much light on the pathology of the disease, has favoured me with the following interesting remarks:—

"I have never seen vaginitis during the eruptive period of scarlatina, nor even among the sequelæ. I am inclined to think that it is an uncommon occurrence. Still, during a smart attack of the eruptive fever, when the mouth, nares, and pharynx are implicated, it seems not unlikely that the inflammatory action should affect the vagina, there being a less abrupt merging of skin into mucous membrane (as in the mouth) than in other mucous outlets. Yet we know that the mouth, nares, and fauces, are specially implicated in this exanthem; and, were the other local affection more common, I think our attention would be drawn to it more frequently. In our dispensary patients, especially among strumous children, muco-purulent discharges from the vagina (slight vaginitis) are common; and I have never had reason to suspect gonorrhœa, though it has been alleged. It is essentially a scrofulous disease of the mucous surface (me judice), and occurs in connection with ascarides, accumulation in the large intestines, as a sympathetic affection, just as otorrhœa occurs during dentition in these subjects.

"Recurring to the vaginitis in scarlatina, I should rather expect it to occur where there had been a very full eruption and good peeling than in any other case. Did not the affection exist before on careful examination of the child's friends, we might safely set it down to scarlatina. But I cannot deem it a specific mark of the disorder, as the mouth, nares, and throat affection, will alone mark the disease without the cutaneous eruption."

I am quite prepared to accede to the opinion of Dr. Tweedie and Dr. Miller, that a muco-purulent discharge from the vagina in scarlatina is a *very rare occurrence*; but this very circumstance increases the importance of the symptom in relation to questions of legal medicine. The more rare the symptom the less likely is it to be recognised as an effect of scarlatina, and the more probable that it will be set down as a proof of contamination.

I will not dwell too much on the two observations I have cited, as I cannot expect they will carry the same conviction to others which they do to myself. I will therefore beg permission to refer to such points in the pathology of scarlatina as seem to give support to the view I have taken of these cases.

1. The inflammatory action in scarlatina attacks a wide extent of mucous membrane as well as skin. It invades a large portion at least of the alimentary tract: the mouth, fauces, pharynx, œsophagus, and, doubtless, sometimes the stomach and small intestines, are affected. The rectum and anus are commonly involved.

The respiratory mucous tract is not less extensively implicated. The nares, larynx, trachea, and even the bronchi, have been repeatedly observed to be inflamed.

The urinary mucous tract is equally affected: the bladder, the ureters, the pelvis of the kidneys, and even the tubuli uriniferi, are involved.

The only mucous tract remaining is the genital. Analogy forcibly points to the inference that this will not be exempted from an inflammation which invades every other mucous tract in the body. I see no reason why the vagina (and also the urethra of both male and female) should not be as frequently and as essentially inflamed as the rest of the mucous membranes.

2. *The discharge.*—A common sequela of scarlatina is an inflammatory thickening of the Schneiderian membrane, accompanied by profuse secretion of an acrid muco purulent matter.

Even before the febrile symptoms are abated, a similar secretion, but generally of a more viscid mucous character, is abundantly thrown out by the mucous membrane of the throat.

A viscid secretion, often containing flakes of lymph, is also frequently coughed up from the trachea. In short,

the obstruction of the throat, mouth and nares, by muco-purulent secretions, is one of the most distressing and alarming symptoms of scarlatina.

Scarlatinal inflammation, then, of portions of the alimentary and respiratory mucous tracts is attended by morbid products similar in character to those attending severe inflammation arising from any other cause.

Ordinary inflammation of the vagina and os and cervix uteri is most commonly productive of mucous or muco-purulent discharges. It is, then, reasonable to expect that scarlatinal vaginitis should produce similar results.

I further believe that a muco-purulent discharge from the vagina may also arise in connection with small-pox, and other exanthematous diseases which affect large tracts of mucous membrane as well as skin.

Such a discharge arising from scarlatina or small-pox may frequently be overlooked; or, when detected, be erroneously attributed to blennorrhagic infection.

I have another observation to make in reference to this subject. Like the discharge from the nares, the vaginal discharge may persist for a lengthened period after convalescence from the fever. It may constitute a new form of leucorrhœa, the true origin of which may never be suspected. In such a case the treatment would be simple. I have found nothing succeed so readily in inducing a healthy action of the Schneiderian membrane, when affected by scarlatina, as the application of nitrate of silver; and I have no doubt that a few injections of a solution of nitrate of silver into the vagina, so as to reach the os and cervix uteri, would effect a cure.

In conclusion, I freely admit that the occasional occurrence of a muco-purulent discharge from the vagina, as a consequence of scarlatina, has yet to be established. Observation alone can decide this.

Extensive inquiry will soon determine the existence of this affection, and the relative frequency of its occurrence. These points established, the practitioner may often experience the grateful opportunity of dispelling unjust imputations against female virtue, and of defeating false accusations of criminal violence.

Gloucester Terrace, Hyde Park, June 26, 1850.

MEDICAL GAZETTE.

FRIDAY, JULY 12, 1850.

Our readers will find, in another part of this number, the first, and we believe the only, instalment on medical legislation likely to be obtained during the present session of Parliament.*

We have great pleasure in giving publicity to this "Act for better regulating the Privileges of the Faculty of Physicians and Surgeons of Glasgow, and amending their Charter of Incorporation," for it breathes throughout a liberal spirit,—using this term in its legitimate, and not in its perverted sense. Under the third clause, the Fellows, Members, or Licentiates of any other Corporation or Royal College may practise in the Glasgow district, and enjoy the same privileges as the Fellows and Licentiates of the Faculty of Physicians and Surgeons of Glasgow. The conduct of the Glasgow Faculty in thus conceding a reasonable privilege, is strikingly contrasted with the illiberality of some other Scotch Corporations and Colleges. The London Apothecaries' Society have been strongly condemned for insisting on their privileges by prosecuting Scotch graduates who have practised in England and Wales without a license; but the following extract from a letter to a contemporary journal will show that illiberality, by which we are here to understand a very rigorous enforcement of questionable privileges, is not confined to the Corporations of England and Wales. If the Edinburgh M.D.s are prosecuted in England, the English Members and Licentiates are persecuted in Scotland. The writer of the letter states, that to his knowledge the Edinburgh University

"would not admit to examination even a member of the College of Surgeons of England, and licentiate of the Apothecaries' Company, and a student of three years' standing at Guy's Hospital, the largest medical school in England, who had also taken out six classes in the University of Edinburgh, and the hospital practice of the Infirmary for a year, and thus possessed certificates of attendance on lectures trebling those required by the senatus of the University. The London students of the same year as myself, who had certificates of lectures delivered at University College and King's College, London, were admitted to examination with only one year's attendance in Edinburgh, whilst the unfortunate Guy's man was thus driven to a northern University for his degree of M.D., unless he chose to stay in Edinburgh two years more. The Apothecaries' Company, in the same year, I know, admitted a friend of mine to examination solely on production of his Edinburgh diploma. I applied to the College of Surgeons of *Edinburgh* to admit me to examination on producing my diploma of the College of Surgeons of *England*. I was refused to be admitted to examination unless I possessed certificates of lectures on all the classes required by the Edinburgh College. Surely this is hardly an act of courtesy, when the London College admits licentiates of the Scotch College to examination solely on production of the Scotch license."

The statement of the writer shows, we think, not merely a want of courtesy on the part of the Edinburgh University and College, but a great want of liberality.

On what principle they draw a distinction between medical students educated at Guy's and St. Bartholomew's, and those educated at University and King's Colleges, we are at a loss to understand. There is no difference in the amount of education imparted, and, as fields of practice, the two great hospital schools, reckoning 1200 beds between them, are superior. This distinction has certainly neither justice nor liberality in its favour.

The Edinburgh Corporations have now a fair example before them in the

* See p. 65.

Act recently obtained by the Glasgow Faculty. If they fail to follow this example, so far at least as to concede a right of examination on the production of an English diploma or license, and still stand upon their ancient privileges, they must not complain if the Apothecaries' Society occasionally put in force *their* rights against the Edinburgh graduates. It is merely an enforcement of the *lex talionis*. The London Colleges have taken the initiative in liberally throwing open their examinations to the possessors of British licenses or diplomas. The Faculty of Glasgow have gone still further: they have instituted an *ad eundem* title; and we think there would be less envy and jealousy in the profession if this plan were more generally adopted. Under a fair dispensation of medical law, the license of one duly constituted College should suffice for a title to practise throughout Great Britain and Ireland.

ALTHOUGH the Assistant Surgeons in the Navy are without any professional representative in the House of Commons, yet their case is not lost for want of an advocate. It is greatly to the credit of some naval officers occupying seats in the House, that they will not allow the grievances of their medical brethren to go unredressed, so long as there is an opportunity of speaking in their favour. In answer to a question put by CAPTAIN BOLDERO on the 5th inst., respecting the steps which had been taken for providing accommodation for assistant-surgeons on board of ships of war, in conformity to the vote of the House on the 8th April last,

"Sir F. BARING said that he had stated, in the course of the debate, that a cabin was dedicated to the service of the assistant-surgeons. On inquiry, it appeared that, although the order was issued by the Admiralty, it was not carried into effect to the full extent. But it was intended that care should be taken that the order should be more

fully carried out. With regard to cabins for the assistant surgeons, the vote of the House would be attended to; but it was not possible by such a vote to add to the accommodation of a ship, and whilst it was the anxious wish of the Admiralty to give accommodation to all officers in the service, yet there were two limits: the first was the efficiency of the ship as a ship of war; and the next was, that they must attend to the accommodation of the crew. In some ships it would be possible to give additional room, and in those ships it was the wish and the direction of the Admiralty that such accommodation should be given to the assistant surgeons; but in others it was not possible, without infringing on the limits he had mentioned. As to the messing, it was his intention that assistant surgeons should be admitted into the ward-room after a certain period—three years of service. On the part of some officers there was more than a doubt as to the wisdom of the vote come to by the House; and, even amongst those who were anxious that additional accommodation should be given, it was felt extremely important for the service that assistant surgeons should at least serve some apprenticeship before they were admitted to the ward-room."

It thus appears that *three months* have elapsed and the order has not been carried into effect to the full extent. It was intended that the order should be more fully carried out. We considered, at the time the vote was taken, that there would be an attempt to evade it by those who, from their official position, would have to carry it into execution. We are, therefore, not surprised at the slow progress made, and the occasional necessity of applying some nautical stimulus to the Admiralty Board. It now appears that a separate cabin will be allotted where this arrangement is possible; while a three years' apprenticeship will be required before admitting the assistant surgeons to the ward-room. To us it appears, that if any novitiate be required for educated gentlemen, one year's service should suffice.

LECTURES
ON THE
TREATMENT OF DELIRIUM AND
COMA;

(IN SEQUEL TO THE LUMLEIAN LECTURES
FOR 1850;)

Delivered at King's College Hospital,

BY R. B. TODD, M.D., F.R.S.

(Reported by Mr. LIONEL S. BEALE, Med. As-
sociate K.C.L.)

LECTURE IV.

Termination of two cases of pneumonia reported in the last lecture—Delirium of bronchitis—Treatment of rheumatic and gouty delirium—Cases—The delirium of erysipelas—nature of erysipelas—treatment—Means of prevention of the delirium—Case—Advantage of the stimulant treatment in preventing secondary deposits—Cases—Sudden coma and death in erysipelas—Cases.

GENTLEMEN,—In my last lecture I spoke of delirium connected with pneumonia, and related to you a case in illustration of the good effects of the stimulating plan of treatment, which is the plan I advise you to follow when you meet with a case of delirium coming on in the course of pneumonia. The boy Hoesley got well under this plan; and after three days the hepatized lung had begun to resolve, and in seven days complete resolution had taken place, and on the tenth day he was restored to complete convalescence.

I mentioned a second case to you,—that of a woman named Darwin, in whom there was double pneumonia, with extreme prostration. We were very anxious about this case when we last met; but I am now able to say that the treatment has proved completely successful, and that the patient is now proceeding quickly to recovery. In this case the delirium did not go beyond a slight wandering at night; and I attribute the almost total absence of delirium to the fact that the stimulants were early and freely administered.

On the 12th of June we found this woman with complete hepatization of the lower two-thirds of the right lung, and slight pleuritic effusion, with a very feeble pulse of 130, and the respirations numbering 44. She was ordered beef-tea and chloric ether. The bowels were opened, and a blister applied to the right side. On the 13th the signs continued the same, with the addition of fine crepitation, which was audible beneath the mamma in front; indicating that the inflammation pervaded

the entire thickness of the lung from behind forwards. She was now ordered six ounces of wine daily. In the afternoon of this day she became so low, and sweated so profusely, that I ordered three grains of quinine in pill every fourth hour, and increased the wine to half an ounce every hour—namely, twelve ounces in the day.

On the 15th she began to expectorate very slightly. The physical signs were unchanged in the right lung; but on the left side, beneath the scapula, there were bronchial breathing and bronchophony, denoting hepatization of the lower half of that lung behind. A turpentine stupe was applied to the back, and half an ounce of brandy was given every hour.

On the 16th large crepitation began to be audible at the base of the left lung; and on the 18th returning crepitation was audible in both lungs. On the 20th the breathing in the left lung had become quite pure. On the right side there was nothing abnormal audible but slight blowing expiration at the base, which soon disappeared.

Thus, in this case, in three days the pneumonia had begun to resolve; and in eight days the lungs had become natural, excepting such a condensation of the right lung as produced the slight expiratory blowing.

The delirium of bronchitis should be dealt with in every way as the delirium of pneumonia. Depression of the vital powers favours the occurrence of delirium; and bronchitis is, generally speaking, a very depressing disease. If, therefore, you should be attempting to cut short the inflammation in a case of bronchitis by active antiphlogistic treatment, you may look upon the occurrence of delirium as the signal for you to alter your treatment, and to adopt a stimulating plan. There is a great tendency in the delirium of bronchitis and of pneumonia to pass into coma; and, unless prompt means are adopted by the physician, the patient dies. This tendency to coma is certainly greater when antiphlogistic remedies have been used. When coma comes on, you must not relax in giving support; indeed, the failure of the pulse or of the heart's action may induce you to be more active in the administration of stimulants; but, in addition to this, you will probably find great benefit from free counter-irritation, by mustard or blister, or both, to the back of the neck; and it may be necessary to shave the head, and apply a blister to the scalp.

Sometimes, but very rarely, the coma coming on suddenly in this way may arise from a sudden effusion of blood upon or into the brain. We had an example of this last week, in the case of a man of 60 years of age, who was admitted into

the hospital suffering under bronchitis, and in a state of active delirium, having been ill about four days. He was a man of intemperate habits, and had probably suffered from privation: however, the bronchitis alone would have been sufficient to have so far disturbed the balance of nutrition as to bring on active delirium. After he had been in the hospital a few hours he became suddenly comatose, and died in a state of profound coma. On examination, it was found that a considerable effusion of blood had taken place into the arachnoid sac, which had diffused itself over both hemispheres. There was also chronic valvular disease of the heart, and there were deposits in the vessels at the base of the brain.

This, then, was a case in which there was a combination of symptoms of a nature calculated to occasion a good deal of embarrassment to the practitioner. The man was intemperate; he had old heart disease, and also severe bronchitis, which greatly impeded the circulation through the lungs. This impeded state of the circulation through the lungs no doubt tended greatly to congest the venous system of the brain as of other organs. And his cerebral arteries being diseased and brittle, it was not difficult to explain their giving way under the increased pressure which they must have sustained from the retarded return of the blood to the right side of the heart.

The case afforded strong temptation for the use of the lancet, or for the abstraction of blood by some other means. But he came to us too late for the adoption of any such measure; and if it were likely that antiphlogistic means would have done him any real good, some change for the better would have ere this shown itself, for such means had already been adopted before his admission in very free purging, to which he was subjected for thirty-six hours. The delirium began on the third day of his illness, and continued until within three hours of his death.

Undoubtedly in this case there was congestion of the brain: but the cause of the congestion was not in the brain, but in the bronchitis; and the best way of relieving the cerebral congestion was to relieve the bronchitis, for which the best remedy was free counter-irritation and moderate support. It is plain that opium was inadmissible, in consequence of the pulmonary congestion.

On the whole, I do not know that we could have done better in this case than what Mr. Jordan did when the patient was admitted,—that is, to have abstained from bleeding, and given moderate support, and applied counter-irritants to the chest. Had he been bled, with the rapid weak pulse

which he had on his admission, he would still probably have died of the coma which arises from a deficient supply of blood, or from the supply of a watery blood.

Rheumatic and gouty delirium.—I shall now proceed to speak of the treatment of the rheumatic and the gouty forms of delirium.

Rheumatic delirium generally comes on suddenly in the course of rheumatic fever, and is frequently *coincident* with pericarditis and endocarditis. I say it is *coincident* with the cardiac affection, and not necessarily related to it as effect to cause; because the amount or severity of the delirium bears no proportion to the intensity of the inflammation; for we may have slight peri- or endocarditis with severe delirium, or we may have slight delirium with extensive inflammation of the heart; and we know well that the cardiac inflammation often exists without the delirium. The severity of the delirium is, however, in proportion to the debility of the patient. When you have a very watery state of the blood, or where the blood is deficient in colouring matter, and when, also, perhaps, the blood is much charged with the rheumatic poison, you have a condition highly favourable to the production of delirium.

The rheumatic delirium undoubtedly occurs more frequently in those cases of rheumatic fever which have been treated by bleeding; and probably because bleeding makes the blood watery, and diminishes its red particles. When I was in the habit of bleeding in every case of rheumatic fever, as I used to do some years ago, a much larger portion of my patients were attacked with delirium than now, when I never bleed in this disease: indeed, now I find it difficult to meet with a case of this form of delirium to show you.

Now let us suppose that you are asked to see a patient who had been labouring under rheumatic fever, and who has suddenly become delirious, with or without difficulty of breathing. From what you now know of the clinical history of the disease, you would at once examine the state of the heart, whether there were any symptoms referable to that organ or not. Let us suppose that you find, as in the majority of cases you will do, a rubbing sound, showing the existence of pericarditis, or a bellows sound, indicative of valvular disease or of extreme anæmia. What are you to do in such a case as this? The patient is quite delirious, tosses about the bed-clothes, talks wildly, tries to get out of bed, and will not be restrained.

Although there is inflammation of the

heart here, and none of the brain, yet I can assure you that the symptom which demands most urgently your first attention is the delirium; and that whatever may be your theory as to the relation of the delirium to the affection of the heart, the interests of your patient demand the instant adoption of means to quiet the state of excitement into which he has passed. Important and serious as is the affection of the heart, as compared with the delirium, it is just now of no moment; for if the delirium be allowed to continue, there is great danger of the patient dying suddenly from exhaustion.

Fortunately, however, we have in opium a remedy equally applicable to the cardiac, as well as to the cerebral affection. In these cases you must give opium to produce sleep, just as you would do in traumatic delirium or in delirium tremens. Opium thus given will quiet not only the brain, but the heart also; and it no doubt exercises a favourable influence on the inflamed serous membrane likewise, checking the spread of inflammation and promoting its resolution.

At the same time, you will find it useful to apply a blister to the region of the heart, and to promote a free discharge from the blistered surface. But avoid bleeding, whether general or topical, if you wish to get your patient through without untoward symptoms, and reserve all other depressing treatment until the symptoms of delirium have passed away. During delirium you must also be careful to administer support, because the very existence of delirium makes great calls on the powers of the patient, and he therefore requires to be freely supplied with nutritious matter easy of digestion, and with stimulants. You need not be deterred from giving opium, and administering support and stimulants, by the fear lest such treatment should increase the cardiac inflammation; the experience of many cases convinces me that under this plan the heart becomes less irritable, the pulse slower, and the cardiac inflammation becomes circumscribed, and it tends to terminate by resolution or adhesion rather than by the effusion of water. On the other hand, if you persist in an antiphlogistic plan, you keep up or increase delirium, you exhaust the powers of the patient, and effusion is apt to take place into the pericardium, whereby the heart's action may become seriously impeded.

If this treatment be commenced early, and pursued effectually, it is rare indeed for the patient to go wrong.

It may, however, be objected to this plan, that patients have been bled, and nevertheless have done well. Undoubtedly this is

the case, and I could refer you to several cases of this description: but although the antiphlogistic plan has been pursued up to a certain point, you will generally find that the obvious exhaustion of the patient has suggested, sooner or later, a change of treatment. But how many cases are there which have ended fatally under the antiphlogistic plan! I might easily collect a considerable number. The first case which arrested my attention as to the inefficacy of the antiphlogistic treatment was one of a young and handsome girl, who had severe rheumatic fever, in the course of which she became highly delirious, and at the same time showed the signs of pericarditis. I treated her for acute arachnitis: the head was shaved, cold applied, mercury freely given, leeches applied to the temples, and the full force of an antiphlogistic treatment was brought to bear upon her. She died; and on examining the head I found the membranes of the brain free from all signs of inflammation, but pale and bloodless.

The treatment of this form of delirium by antiphlogistic means is, in my opinion, as inexpedient and as dangerous as that of delirium tremens by a similar plan; and we are not justified in assuming that the practice is safe or desirable because cases have got well under it.

I have but little to say upon the delirium which accompanies acute gout, because the remarks I have made upon the rheumatic delirium are equally applicable to it. I shall content myself with stating that, while the delirium is essentially of the same nature as the rheumatic, it has a greater tendency to pass into coma. While, therefore, our treatment ought to be in all other respects of the same kind, we must not be so ready to administer opium as in the rheumatic delirium; we should wait to observe whether there is any marked tendency to coma. I had a well-marked example of this form of delirium in one of the College porters, a stout lusty man, who used to attend the gata. After having had several attacks in the great toe, he had a very severe attack of general gout, resembling very much rheumatic fever, but without any inflammation of the heart. He became violently delirious, so much so as to require restraint. I was called to him in this state, and prescribed stimulants, and treated him much in the same way as if it were a case of delirium tremens; but I did not give him opium. He took hyosciamus, and after a time, as there appeared to be no tendency to coma, I ordered him small quantities of opium. He soon improved, and got rapidly well.

In the delirium of rheumatism and gout we occasionally meet with cases of sudden

death from exhaustion: the patient, after an effort, suddenly falls back dead. Hence, when delirium shows itself during rheumatic fever or acute gout, the attendants of the patient should be warned of this danger, and distinctly instructed to watch the patient closely, so as to prevent as much as possible all exertion, and to keep him in the horizontal posture.

One point I wish particularly to impress upon you is, that as in pneumonia, and in cases of severe injury, you may prevent the delirium, so also in rheumatic fever and in acute gout you may keep it off by avoiding extreme antiphlogistic measures, under the idea of cutting short the disease. I am convinced it is an erroneous notion, to which careful clinical observation gives no countenance, that such a disease as rheumatic fever may be cut short by a bold stroke of the lancet. There are mild cases as there are severe ones, and it is not easy to distinguish the one from the other at their onset. The practitioner, therefore, who bleeds as a matter of routine, will often meet with cases which will *appear* to have been cut short by such a practice. And even if you do cut short the disease by the sudden abstraction of a large quantity of blood, it will be at a tremendous cost to the patient, involving years of subsequent delicate health.

Our object in the treatment of these cases should be, not so much to cut short the disease by debilitating the patient, but carefully to guide him through the malady, promoting the elimination of the morbid poison, and at the same time protecting his powers against its depressing influence. By this mode of proceeding we do not pretend to cut short the disease, but we shall guide our patient safely through it, and shall much shorten the period of his convalescence.

The delirium of erysipelas.—The next subject to which I shall call your attention is the mode of treating the delirium of erysipelas. I know no disease the pathology and treatment of which are more worthy of the careful consideration of the practical physician or surgeon than erysipelas, as it is a malady of very frequent occurrence, and very severe and destructive in its nature. The question of the treatment of the delirium of erysipelas involves the consideration of the treatment of erysipelas itself. I refer here of course particularly to the idiopathic erysipelas, which comes under the observation of the physician; but the remarks I have to make will apply equally to the phlegmonous form which you will meet with in the surgical wards, for the two forms of the disease are of essentially the same nature,

Let me begin by stating what appears to me to be the most reasonable view of the nature of erysipelas, and the most consonant with its clinical history. Erysipelas is produced by the introduction into the system of a morbid poison, generated in the body under certain circumstances, or derived from another individual affected with the disease. A patient who has received an injury may generate the poison of erysipelas in his own person by exposure to certain deleterious influences; or he may, under similar circumstances, generate this poison in his own body, even when he has not received any wound, in which case we call the erysipelas *idiopathic*. Or whether wounded or not, he may imbibed the poison from some one labouring under the disease, even without actual contact.

The poison of erysipelas, like that of measles, of small-pox, of scarlet fever, &c., has its special habitat,—that is, it shows a proneness to affect certain tissues to the exclusion of others; and it attacks specially the skin and the gastro-pulmonary mucous membrane, sometimes affecting the throat first, and travelling outwards to the skin; at other times taking the contrary course. This poison produces other effects than mere cutaneous inflammation; its introduction into the blood causes a fever of a very depressing nature, and this amount of depression bears no constant relation to the extent of the cutaneous inflammation. A large dose of this poison may kill a patient in a few hours, causing at the same time only very trifling local disturbance, such as a trifling redness of the throat. Generally speaking, however, it requires many days for its elimination, during which time the patient exhibits the local and constitutional symptoms with which you are familiar.

Like the other morbid poisons to which I have alluded, the poison of erysipelas exhibits secondary and tertiary effects: secondary effects in the formation of abscesses in various parts of the body, and even in parts which may not have been affected by the cutaneous inflammation; and tertiary effects in chronic inflammation and induration of various glands, and the deposition of scrofulous matter.

What is the most reasonable and the best treatment of erysipelas? have we any means of eradicating the poison by a bold stroke at the onset of the disease? Slight cases—or, in other words, cases which have imbibed only a small dose of the poison—will quickly recover, with little or no medical treatment; and such cases, when treated early by a bold antiphlogistic measure, will appear to have been cut short. But, in the majority of cases, when a large dose of the poison has been imbibed, I believe that

the disease must pass through a certain course, that the poison will produce its specific effects, and that the principal business of the practitioner is to uphold the powers of the patient so as to limit as much as possible the destructive influence of the poison. In such a case you can no more think of extracting the poison by some active stroke of treatment, than you can think of eradicating the poison of small-pox or scarlet fever under similar circumstances. Any one who would, now-a-days, think of such a thing in these maladies, would be set down as having lost his senses. We have no means of extracting the poison; we must, therefore, endeavour to guide our patient through the various stages of the fever it excites, into port, or we must find some antidote for it, which, when introduced into the blood, may counteract its depressing and destructive effects.

There is no treatment which appears to me to be so generally applicable and so safe in cases of erysipelas, as that which we call the stimulating treatment—by support by means of nutritious food in the liquid form, and by bark, or ammonia, or chloric æther; nor is there anything which seems, in some cases most strikingly, to act so much as an antidote to the erysipelatous poison, as alcohol, given either as brandy or wine, or beer, but more especially as the first.

In all cases of erysipelas, then, my practice is first to evacuate the bowels, when necessary, by such means as will not occasion any undue depression, and then to give nutritious food, easily digestible, with stimulants, as brandy or wine. I adjust the quantity of these according to the urgency of the symptoms, keeping, however, to this rule—namely, to give small quantities very frequently, and at short intervals, rather than larger quantities administered occasionally. This is, if I may use the expression, the staple of my treatment: to it I add such medicines as ammonia, bark, &c.; but if the stomach be irritable, or the patient opposes or is disgusted with the administration of so many things, I prefer giving up the drugs and trusting to food and brandy only.

Patients treated in this way from the beginning do not often become violently delirious. When delirium sets in in erysipelas, it may be taken as an indication that our patient wants more support and more stimulus; and the more quickly and freely you give them under such circumstances, the sooner you will subdue the delirium. If freely given just at the beginning of the delirium, you may check it completely. Of this I had a remarkable example last summer, in the case of a

clergyman, a robust man who came to town with his family to see the lions. He caught cold, as he thought, from sitting one hot day, with a north-east wind, near an open window in an omnibus. That evening he had a severe rigor, and vomited. I saw him soon after, and found some redness of the mucous membrane of the nose, spreading outwards on the skin. I immediately suspected erysipelas, and the next day confirmed my suspicions, as the redness had extended over the nose. He was moderately purged, and to his surprise I allowed him two or three glasses of port wine at once. Under this treatment he seemed to go on well for a couple of days. One night I was led almost by accident to visit him at a very late hour; and to my surprise he was looking strange, talking rather wildly, and wanting to get up and go out. I immediately called for the brandy bottle, and gave him a large dose of it, which seemed to quiet him; and I left instructions with the nurse to give him smaller quantities at short intervals through the night. Next morning I found that he had slept through the greater part of the night, and that the delirium had completely ceased.

In cases which show a tendency to coma, it is often advisable to shave the head and apply blisters freely to the scalp or back of the neck. Nor need you be deterred from applying blisters, by the fear lest the blistered surface shall become the seat of new erysipelas. As a rule, it is not desirable to give opium in the delirium of erysipelas, unless the delirium is decidedly of the active and wakeful kind; on the whole, however, the other narcotics, as henbane, camphor, hop, are safer than opium.

The stimulating treatment in erysipelas not only saves the patient from delirium, or cuts it short when it appears, but it shortens the period of convalescence, and, what is very important, it seems to diminish the tendency to secondary deposits. We have had many cases in the hospital which exemplify this remark. You may recollect a very severe case of erysipelas last winter in Lonsdale ward: the patient was quite delirious, and there was afterwards a tendency to coma; nevertheless, this patient quickly recovered, and had no secondary abscesses: she was treated by stimulants from the beginning. In Augusta ward, also, we had a similar case about the same time, which was treated in the same way with a like result. The clergyman's case, to which I just now alluded, afforded another example of the absence of secondary deposits under stimulating treatment, although the erysipelas extended over the whole scalp. His wife, on the other hand, who caught the disease from him, had a

very irritable stomach, and could not take stimulants; and she had an abscess in one of the upper eyelids. In the case of a young lady whom I attended in the spring, along with Mr. Bowman, with severe erysipelas, there were no secondary abscesses; she was treated by brandy and nourishment from the beginning; and I could enumerate several other instances in which this desirable result followed the stimulating treatment.

Now and then it will happen that an erysipelatosus patient will rapidly become comatose, and die in spite of all our remedies. There was a man in Sutherland ward a short time ago, affected with erysipelas, who appeared going on very well for some time, but suddenly he became comatose, and died, and we could not make out any reason for his death. The only reasonable explanation that I can offer of the sudden change for the worse which sometimes occurs in these cases, is derived from the well-known tendency they have to form pus, which, accumulating at some point, may find its way through the ulcerated coats of some small vein, and thus enter the circulation, producing coma and complete prostration.

I shall conclude this lecture by referring to two cases as examples; the one to show the rapidly fatal influence of the poison of erysipelas, and that the extent of the cutaneous affection bears no relation to the effects of the poison on the system; the other to illustrate the good effects of an early stimulant treatment.

The first case is that of a man named Collins, *æt.* 27, who was admitted into the hospital about three weeks ago. He had always been temperate in his habits, and enjoyed good health, with the exception of an attack of erysipelas two years previously.

On the 28th of April he noticed a small pimple on his nose, which increased rapidly in size, and on the first of May, having been exposed to cold, he was seized with shivering. He entered the hospital on the 3d of May. The inflammation had spread on the nose and great part of the face and the eyelids, but not so as to close the eyes. He was ordered five grains of carbonate of ammonia every three hours. On the 4th he was evidently much lower; several pustules full of pus had formed upon the nose; but the erysipelas had not spread. Brandy was ordered to be given freely, and chloric ether added to the ammonia. That night, however, he began to breathe quickly, and became comatose, and died on the fourth day from the rigor. It is very probable that had stimulants been administered from the first in large quantities, this patient might have been saved. I confess

that when I first saw him I was not impressed with his being in so low a state.

Upon examination we could find no evidence of inflammation or of any other morbid state of the membranes of the brain; but there were recent adhesions on the right side of the chest, and, as commonly happens, there were signs of recent inflammation of the mucous membrane of the bronchial tubes. This case shows you how rapidly a man may be knocked down by a large dose of the poison, although the external signs by which the disease is distinguished may be very slight.

The second case to which I shall refer is that of Jones, *æt.* 44, which terminated favourably, although in some degree placed under less favourable circumstances than the former.

This man's habits were intemperate. When admitted, he had very extensive erysipelas of the head and face; the eyelids were closed; the tongue dry and brown. This was on Saturday, the 27th of April. He was immediately ordered chloric ether; beef-tea, two pints, and brandy, two ounces per diem. On the 28th and 29th no material change had taken place. The brandy was increased to six ounces on the former day.

April 30.—On the evening of the 29th he became extremely restless and delirious, and it was with great difficulty that the nurse and some of the convalescent patients in the ward could keep him in bed. His allowance of brandy was doubled, half an ounce to be taken every hour, and half a drachm of chloric ether every two hours.

The next day (May 1) it was reported that the pulse had fallen to 92 from 100, and that the delirium had ceased. On the 2d of May he was reported to have passed a very good night without any opiate, and was perfectly rational. The pulse had fallen to 76: this was a most favourable sign. It is especially auspicious when the pulse falls in frequency while the patient is taking stimulants.

From this time this patient recovered rapidly, without the occurrence of any purulent deposits.

This case shows how, by increasing the amount of stimulants, you may subdue active delirium and shorten convalescence; for on the 4th of May this patient was well enough to eat meat. The attack began on the 27th of April, so that in seven days he passed through the various stages of a severe attack of erysipelas, and became convalescent.

At our next meeting I propose to consider the treatment of the delirium of typhus fever, and the delirium of hysteria and of epilepsy.

Rebiews.

The Types of Delirium Tremens, their Pathology and Treatment. By JAMES BIRD, A.M., M.D. Pamphlet, 8vo. pp. 29. London. 1850.

THE treatment of delirium tremens has been attended with difficulty and uncertainty, because it has not been sufficiently borne in mind that it is a disease susceptible of considerable modifications, and often complicated with various and even opposite states of the system. Dr. Bird's object is to point out the varieties thence resulting, and the practical application of their distinction in the treatment of the disease, as observed by himself in the European General Hospital at Bombay, during a residence of four years.

The author describes four types, or forms.

1. *The simple*, or "purely nervous variety, depending on mere erythsm of the nervous system, either of centric or peripheral origin, which runs a certain course, and has a tendency to subside of itself in a given time."

Dr. Bird's experience leads him to fix from four to six days as the average duration of this form of the disease.

2. *The inflammatory*, "marked by a degree of vascular determination to the brain and its connections, or to some of the remote organs, either the stomach or lungs, which may act sympathetically on the nervous system."

3. *The pyrexial*: "occurs more generally in the malarious seasons of the year, from July to October, is frequently met with during the other months, in constitutions rendered irritable by long residence in warm climates, or in persons previously subject to intermittent and remittent fevers."

4. *The epileptic*, "attended with convulsive twitching of the muscles, passing into sudden loss of consciousness and sensation, accompanied by clonic spasms of the muscles, recurring in paroxysms, which terminate in recovery of consciousness and sensations, or in apoplectic annihilation of the cerebral functions."

Tabular statements, illustrative of these several forms of the disease, are given by Dr. Bird. The author also adds observations on the causes and diagnosis of this disease. It appears from the latter, that in India it is not unfrequently mistaken for poisoning by

Datura, the symptoms of which, in some points, resemble those of delirium tremens. Dr. Bird observes on this subject:—"The diagnosis of the simple erythsmal type of delirium tremens, from like cases of narcotic poisoning, will be found in the history and development of the two diseases from their respective causes; in the persistent *insomnia* of the one, contrasted with the somnolency, or, rather, *somnambulism*, of the other; in the manner of the patient, which is busy and active in the former, sluggish and inactive in the latter; in the *greater power of controlling the thoughts* for a moment, which persons labouring under drunken cerebral erethism possess over those who are narcotised by stramonium; and in the *more busy character of the delirium* of the first, compared with the drowsy, low muttering, and catching at objects of the last."

The author's remarks on the subject of treatment are highly judicious. They are directed to the abolition of the indiscriminate employment of opium, and teach the importance of following the indications of the pathological conditions of each case.

Handbuch der allgemeinen und speciellen Gewebelehre des menschlichen Körpers, für Aerzte und Studierende. Von Dr. JOS. GERLACH. Dritte Lieferung. 8vo. Mainz. 1849.

THE part now before us concludes the publication of this very excellent compendium of general and special human anatomy. The subjects comprised in this portion of the work are, the generative organs, the nervous system, and the organs of the senses. Having on former occasions spoken well of the two preceding portions, we need only now reiterate our commendations. We can safely recommend Dr. Gerlach's Handbook to every student who may desire to gain a knowledge of the present state of physiological anatomy. As an acquaintance with German medical literature will henceforth be a *sine quâ non* to a complete professional education, we would advise the student to take Dr. Gerlach's work as his companion in his study of German medical authors. While acquiring a knowledge of the language, he will at the same time derive from this work a large amount of valuable information on the topics with which it is more immediately occupied.

THE PRESIDENT IN THE CHAIR.

A Case of Ileus and Strangulated Hernia occurring in the same Individual. By SAMUEL SOLLY, F.R.S., Senior Assistant-Surgeon to St. Thomas's Hospital.

THE patient was a fine young man, aged twenty-one. Mr. Solly found him, at half-past ten A.M., writhing on the floor in great agony. He had an inguinal hernia on the right side. The account which he gave was, that the swelling and pain occurred simultaneously on going to the water-closet immediately after breakfast. About ten days previously he had obstinate constipation, for which he took some strong aperient medicine, which, when acting, produced a good deal of pain, and left considerable irritation of the bowels, that lasted some days, the evacuations being tinged with blood; but this all passed away, and on the Sunday before the Wednesday on which he was seen by Mr. Solly he took a walk of fifteen miles without feeling any fatigue. On the Tuesday night he made a full supper of stewed beef, and on the Wednesday morning again ate of the same dish, and so heartily that he acknowledged to his friend that he had eaten too much. As he left his home after breakfast, at half-past eight A.M., and was descending the steps of his house, he complained to his friend of a violent pain in his belly, having at that time a swelling in the groin; this pain was so severe that he was obliged to ride up to town, and by the time he reached his destination, in Leadenhall Street, he was deadly pale, and his lips blue with pain. On his arrival he went to the water-closet, and passed some faeces, and in so doing the swelling first appeared in the groin. He says it came down without any pain. The taxis proved unsuccessful, and the hernia was so very sensitive, that he was removed to bed, and ordered a warm bath, and in the meantime ice to be applied. In an hour's time, the ice having produced no effect, the taxis was again tried, but very gently, without avail. The warm bath was next used, but with the same result. Mr. Solly now determined to operate, just four hours after the descent of the rupture. The external and internal rings were divided. The external abdominal ring, which was very tight, was divided without opening the sac, but as this did not release the intestine,

the sac was opened; in it there was a knuckle of gut, which was forced over the external ring, and was of rather a dark colour, and another portion of intestine, at the lower part of the sac, was almost healthy. The internal ring was next divided, and the intestine returned without difficulty into the abdomen. The wound was dressed in the usual way. The post-mortem examination was made the morning after his death, at 9 A.M. The abdomen only was examined. The external and internal rings were found quite free; there was about a foot and a half of small intestine, enormously distended, and nearly black, lying in the pelvis; on raising this, it was found girt by a band about an inch and a half long, which was connected with the cæcum on the one side, and with the peritoneum covering the iliacus internus muscle, close to the internal abdominal ring, on the other: this band was round and firm, and seemed to be either one of those bands of old adhesive inflammation which are occasionally met with in the abdomen, or the remains of the omphalo-mesenteric duct. It must have existed a long time. It was not so tight as to have strangulated the intestine in its undisturbed condition. Mr. Solly believed that this was the cause of the previous obstinate constipation, and also the cause of the subsequent irritation of the bowels, though it all subsided before the fatal strangulation took place which terminated his existence.

ROYAL SOCIETY.

May 30th, 1880.

THE EARL OF ROSS, PRESIDENT, IN THE CHAIR.

On the Structure of the Dental Tissues of Rodentia. By JOHN TOMES, Surgeon-Dentist to the Middlesex Hospital. [Communicated by WILLIAM BOWMAN, Esq. F.R.S.]

THE author of the paper bearing the above title relates the results obtained from an extensive series of investigations on upwards of sixty of the more typical members of the order Rodentia. He finds that not only are the teeth of animals of this order distinguished by strongly-marked structural peculiarities (hitherto not recognised) from other mammalian teeth, but also that the teeth of the several larger groups are distinguished from each other by modifications in what may be called the rodentia type of dental tissues. Mr. Tomes pointed out, in a paper published in Part 2, for 1848, of the Philosophical Transactions, that in the teeth of marsupial animals the dentinal tubes are continued into the enamel. In

the present communication he shows, that the structural peculiarities which characterize and are confined to the teeth of rodents are also mainly resident in the enamel.

The earlier pages of the paper are devoted to a description of those structural conditions which are common to the teeth of the whole order.

Amongst these the author finds, that the extremities of the dental tubes, which in the lower part of the tooth communicate with the pulp-cavity, become, in the extruded portion, sealed up by the development of a layer of non-tubular tissue, which is formed at and near the apex of the pulp-cavity. This closure of the dental tubes is not, however, confined to the teeth of *Rodentia*, but occurs in all teeth in those parts exposed to wear. A similar condition is found to obtain in the osseous tissue which forms the antlers of the deer tribe. If a portion of an antler, previous to its losing its periosteum, be examined, ordinary Haversian systems are found; but if an antler which has been shed be examined, each of the larger Haversian systems will be found to be lined by a layer of transparent tissue, destitute both of lacunæ and canaliculi.

The author considers these conditions to indicate the existence of a general law, viz. that dense tubular tissues, when about to be exposed to wear, or about to be cast off, are first deprived of their connection with the nutrient fluids by the development of a layer of non-tubular tissue between them and the vascular surface, with which they were originally connected, and from which they derived their nutriment.

In order to facilitate description, Mr. Tomes proposes to use several terms as indicative of the number and arrangement of the component tissue of teeth. Thus a tooth which has one central pulp-cavity, from which the tubes radiate to all parts of the dentine, he terms a *dental system*; and if this be coated with enamel, partially or wholly, a *denticle*. A tooth composed of several dental systems, each of which are more or less invested with enamel, and the whole united into a mass by cementum, he describes as a tooth composed of *denticles*; but if the dental systems are united without the intervention of enamel or cement, as a tooth composed of *dental systems*. If the systems are united to each other throughout their length by a narrow band of dentine, the tubes of which belong as much to the one as to the other adjoining system, the tooth is said to be made up of *confuent dental systems*; but if each system is partially coated with enamel, of *confuent denticles*.

The tooth of the *Labyrinthodon* is mentioned as being composed of confluent

dental systems, with an external investment of enamel common to the whole. He objects to this tooth being described as divided into compartments by inflections of the cementum, because the division into dental systems takes place internal to the enamel, external to which the cementum would be placed if there were any in this part of the tooth.

A minute description of the dental tissues of upwards of fifty species of rodents forms part of the paper. They are taken in the order proposed by Mr. Waterhouse in his arrangement of rodentia, published in Johnston's Physical Atlas. The author has followed this arrangement because he finds that it accords with the modifications of the dental tissues. The incisors are described as possessing the most strongly-marked and constant characters.

The enamel of the incisors of rodents has been described by Prof. Owen as composed of two layers—an inner placed next the dentine, and an outer, which extends towards the surface of the tooth. Mr. Tomes objects to this description, on the ground that the fibres of the inner and outer division are continuous. This change of direction and arrangement does not occur in the hare tribe.

The anterior surface of the incisors of many rodents has a deep brown colour, which has been attributed to the presence of a layer of coloured cementum. The author states, that the enamel fibres can be traced through this coloured part to the surface of the tooth, and hence regards the colour as a stain resident in the terminal ends of the fibres, and denies the presence of cementum in this part of the tooth.

The great distinguishing structural feature in this order of quadrupeds consists in a lamelliform arrangement of the fibres of the enamel in the inner division of that tissue.

In the *Sciuridae*, the enamel is composed of parallel layers of fibres, and each layer of a single series, which, in the contiguous layers, pass in contrary directions, so as to give a square pattern to the inner or lamelliform portion, when seen in a transverse section of the tooth. In the outer part of the enamel the decussation ceases; the fibres suddenly change their course, become parallel, and proceed upwards in straight lines to the surface, but without any indication of lamination. In a longitudinal section, the laminae are seen to lie at right angles to the surface of the dentine. This peculiarity of position the author finds to be constant in the squirrel tribe and marmots, but he has failed to find the same angle preserved in the members of any other group.

In the rat family, *Muridae*, a similar lamelliform arrangement of the fibres is present in the inner enamel, but the laminae lie

surface of the dentine, and, as seen in a longitudinal section of an incisor, have well-marked serrated edges. The fibres are generally oval in their transverse section, but when exposed in their length have slight serrations from what may be regarded as their upper and lower surfaces. These little processes occupy the intervals left by the oval figure of the fibres of the layers situated immediately above and below.

The incisors of the Gerboa (*Dipus Egyptianus*) and Dormouse (*Myoxus avellanarius*) show the serration of the laminae, but indistinctly, and are otherwise peculiar in having the layers of the enamel fibres in the lower incisors extended in the length, while those of the upper teeth are placed across the tooth, just as in the squirrel and in the more typical rats. Hence in these creatures a longitudinal section of a lower corresponds in appearance with a transverse section of an upper incisor.

In the rootless molar teeth of the members of this extensive family of rodents, the enamel corresponds in its lamelliform arrangement with that of the incisors; but in the rooted molars, the laminated character is seen near the terminal edge of the enamel only. In the molar teeth of the Gerboa, the dentinal tubes are continued into the enamel, in the same manner as in the teeth of marsupial animals.

In the members of the Hystricine family, Mr. Tomes finds that the enamel presents an appearance very different from that observed in the teeth of the preceding groups. The fibres take a serpentine course, and describe several uniform curves in the inner part of the tissue, the number and size of the curves varying in the different species. Notwithstanding this peculiarity, the fibres are disposed in laminae, which run transversely across the tooth.

In a longitudinal section of an incisor, the laminae appear thick and confluent; while in a transverse section parallel to the course of the fibres it is seen that the curves of the fibres of contiguous layers take an opposite direction, but that those of alternate layers follow the same course. It is moreover seen, that the curves of the fibres, when regarded in the whole breadth of the enamel, are arranged in series, which commence at the surface of the dentine, and instead of following the surface of that tissue in colour, lines proceed obliquely outwards, and cross out near the surface, where the fibres become straight and parallel, and lose their lamelliform arrangement.

This curved disposition of the fibres gives to the enamel, as seen in the longitudinal section, an extremely complex appearance.

In the molar teeth of Hystricine rodents, the author finds a similar arrangement of the enamel fibres, but with the characters

of group less strongly marked than in the incisors, and subject to modifications in the different species.

The *Brathyrgeus maritimus* is found to have teeth structurally similar to the Hystricine family, with which it has been placed, but is now separated, and located in the last section of the *Muride*.

The *Helamys Capensis*, though placed in the rat family in the arrangement which the author has followed, appears, in its dental structure, to be closely related to the Hystricine animals, and in the minor degree to the hare tribe.

In the *Leporidae*, a family containing forty-six species only, and therefore numerically unimportant as compared with the preceding groups, which collectively contain 558 species, Mr. Tomes finds that the incisors differ in structure from those of the preceding families, in uniformly possessing vascular dentine, and also in having the fibres of the enamel continued in an uninterrupted course from the surface of the dentine to the surface of the tooth, and without the slightest indication of an outer and inner division similar to that which forms so constant a character in the incisor teeth of the preceding groups. The lamelliform arrangement of the enamel fibres is broken and indistinct, and their decussation, as seen in a transverse section, is irregular.

In the molar teeth of the hares, the enamel fibres, where the tissue is tolerably thick, proceed through the first part of their course in straight and parallel lines, but afterwards describe one or two large curves, and with an irregular lamelliform arrangement.

The author remarks, that the enamel in the teeth of the *Leporidae* bear a close structural resemblance to that of the teeth of the Wombat, described and figured in his previous communication to the Society, and that the structure of the dental tissues generally is more closely related to those of the *Hystricidae* than to any other rodential family.

The paper was illustrated with numerous figures, drawn from the more typical species of rodents.

It is stated at the conclusion, that the author purposes, in a future communication, entering into the development and special adaptation of the peculiarities of the dental tissues which it has been the business of this paper to lay before the Society.

ACADEMY OF MEDICINE, PARIS.

Medico-legal Researches on Dried Cerebral Substance.

M. ORFILA read an essay on this subject, with reference to a late assassination. M.

Orfila, with M. Jules Bares, had been requested to state whether a certain substance, adhering to the *blouse* of the accused, consisted of dried cerebral matter. From the smallness of the quantity of this matter, and the want of recorded investigations on this question, the inquiry was beset with considerable difficulty. From their experiments M. Orfila submitted the following conclusions on this very important medico-legal investigation :—

1. Among the organs of the human body the brain has a peculiar and specific reaction with sulphuric and hydrochloric acids.

2. The pancreas, digested in concentrated sulphuric acid, imparts in a day or two a violet tint, analogous to that presented by cerebral matter; but this violet tint has been preceded by a yellowish-brown and then by a red hue, which do not occur with cerebral substance. Besides this, the pancreas imparts to hydrochloric acid a dull slate-grey colour, without any violet tint; this also does not occur with cerebral substance.

3. Muscle imparts a violet tinge to sulphuric acid, at the end of a day or two, but this has likewise been preceded by a red tint. With hydrochloric acid the reaction is similar to that of pancreas.

4. The substances which, adhering to garments or to weapons, might be mistaken for cerebral matter, are, for the most part, white of egg, butter, soft cheese, gelatine, and fat. But these cannot be confounded with cerebral matter if submitted to the action of sulphuric and hydrochloric acids.

5. Albumen imparts a violet colour to concentrated sulphuric acid, but with hydrochloric acid a blue colour is produced, as deep as that of ammoniaco-sulphate of copper; exposed, however, to heat, a violet colour results, which passes into deep (purple) brown. The cerebral matter, on the contrary, does not dissolve in hydrochloric acid, even after twelve days; at the end of several days it presents a slate-grey tint, passing faintly into violet, and then to a red, without exhibiting any trace of blue.

Cheese produces a violet colour when dissolved in sulphuric acid, but it may be distinguished from cerebral matter by the ready precipitation of the latter on the addition of water. Cheese, also, is precipitated of a black colour by chloride of nickel; while cerebral matter is thrown down of a green colour, by this reagent, from its solution in sulphuric acid.

Dissolved in hydrochloric acid, cheese that has been dried by the sun presents almost immediately a clear rose, then a violet, and lastly a dull grey colour; whilst

brain produces no discoloration for a long time, and then passes to a grey with a very slight violet tint.

6. It was not possible to detect the phosphorus of cerebral matter in so minute a quantity as was presented for examination.

7. Acetic acid was of no use in the experiments.

8. Sulphuric and hydrochloric acids suffice to distinguish cerebral matter from albumen, cheese, &c.

The microscope (of 580 to 600 diameters) detected a very minute quantity of cerebral substance, and confirmed the chemical analysis. The blood-globules may also be distinguished by the microscope if the substance, or article to be examined be first treated by a concentrated solution of sulphate of soda.

. The chemical differences here assigned require further investigation before they can be adopted in practice. This remark especially applies to the action of hydrochloric acid on the cerebral substance.

Influence of Vaccination on Population.

M. BOUSQUET read a paper in which he refuted the assertion of M. Carrot, that vaccination is the cause of typhus, phthisis, &c. in youth; and that consequently, in saving the lives of infants, it only preserves them for certain death at a more advanced age.

SURGICAL SOCIETY OF PARIS.

June 19th and 26th, 1850.

THE discussion on M. Chassaignac's proposed new treatment of abscesses was concluded. M. CHASSAIGNAC submitted his plan as the result of his experience in numerous cases, and invited the members of the Society to make their own experiments thereof.

Amputation of the Tonsils.

M. GUERRANT presented Fahnestock's new instrument, which permits the performance of this operation with such facility and rapidity, that it may be performed upon the most intractable child without assistance.

MM. LARREY, CHASSAIGNAC, and LENOIR, considered that the usual mode of amputating the tonsils is preferable to the employment of so complicated an instrument as that submitted by M. Guerrant.

New Forceps to supersede Museux's.

M. LARREY presented the forceps invented by M. Luër, and which have been

used with advantage by MM. P. Dubois and Maisonneuve. Instead of terminating as crotchets, the ends of the branches presented two rings, which joined on the blades being closed. A toothed rack was attached to maintain the branches in a fixed position.

*** We are at a loss to comprehend from this description the mode of application, and the superiority of these forceps.

ACADEMY OF SCIENCES, PARIS.

June 24th, 1850.

The Diet of the Miners of Charleroi.

M. MAGENDIE read a letter from Dr. Charpentier, of Valenciennes, in which it was stated that the account of the diet of the miners of Charleroi, given by M. Gasparin on a previous occasion, was not in accordance with his own observations.

It is true, observed M. Charpentier, that the miners subsist on the coffee and bread-and-butter diet, described by M. Gasparin, when in the shaft; but they do so because a more substantial diet is digested with difficulty in the painful and constrained posture they are obliged to maintain in the galleries. At other times these men make use of a meat diet, with beer, brandy, &c.

With reference to the health of these workmen, Dr. Charpentier quoted the report of the Inquest by the Belgian Government,—that they manifest all the usual effects of the excessive use of some muscles and the total disuse of others; besides which, their constitutions are so impaired, that at the ages of thirty or forty years they become the subjects of fatal disease. The superiority which certainly exists in the health of the miners of Charleroi over that of the labourers in the mines of Mons, Liège, and Anzin, M. Charpentier traced to the difference in their mode of ascent and descent to the mines. In the last-named mines the workmen are extremely fatigued, and fatal affections of the heart are induced by the method of ascent and descent.

Dr. Charpentier added that he had investigated this subject because the statement of M. Gasparin appeared so contrary to all that chemistry has taught, and because he attributed the frequency of phthisis, &c., to the low vegetable diet of the labouring classes in France. Dr. Charpentier accounted for the greater amount of labour of which English workmen are capable, by the superiority of their diet.

Some points in the History of Fecundation in the Lower Animals.

M. QUATREFAGES read a paper in which

he stated that the experiments of Spallanzani, and of Prévost and Dumas, on the spermatozoa and ova of Batrachians, are few in number, and from their having been performed on fresh water animals, the results do not admit of generalization.

M. Quatrefages had endeavoured to supply the deficiency by a series of researches on *Annelida* and *Mollusca* living in salt water. The author had studied the influence of increase and decrease in the saltiness of the water,—the action of acids, bases, and salts. The following are some of the results at which M. Quatrefages had arrived:—

The spermatozoa of the Hermaphrodites bear a decrease, better than an increase of the saline matters of sea-water. The bases exert a less influence than the acids. Organic poisons act much less energetically than mineral poisons. Among mineral poisons the nitrate of copper and acetate of lead exert an equal influence; while corrosive sublimate acts more energetically upon the spermatozoa of the *teredo* than on those of others. In all aquatic animals having an external fecundation, a certain degree of dilution is required for the fecundating liquid to attain the maximum of its power. In the Batrachians, beyond a certain limit the number of fecundated ova is in proportion to the number of spermatozoa. The immediate contact of the ovum and of the spermatozoon is necessary to fecundation. The spermatozoa, which have been apparently killed by some noxious agent, are capable of restoration to activity. Contrary to that which obtains with Batrachians, the ova of the *teredo* are capable of fecundation after long residence in water not containing any spermatic fluid. A slight increase in the saline ingredients of sea water prevents fecundation in the ova of *teredo*. The addition of a small quantity of fresh water favours fecundation and development of the larvæ. The action of poisons is less energetic upon the larvæ than upon the ova and spermatozoa.

FRACTURE OF THE SKULL.

THE uncertainty of the trephine, as a means of cure, was demonstrated in the case of an unknown man, who died a few hours after admission. The fracture was in the base of the skull; but the principal coagulum, which was of great size, was on the opposite side, and in the upper and middle portion of the cerebrum.—Dr. Hartshorne, in *American Journal of Med. Sciences*, 1850.

Hospital and Infirmary Reports.

KING'S COLLEGE HOSPITAL.

Hernia—Stricture—Taliacotian operation.

In a former report from this hospital (see MEDICAL GAZETTE, May 31), was a case in which Mr. Bowman had operated for femoral hernia: we mentioned that, on the 25th of April, fecal matter was coming away from the opening made to relieve the stricture. On May 1, the powers of the patient had begun to give way; she was beginning to lose flesh; she had a troublesome cough; the tongue had become furred and dry; pulse 100, feeble; patient lying in a sleepy condition: she, however, took nourishment well, and did not vomit. The wound looked ill: the sac commenced to slough; and a portion of the intestine could be seen exposed, and in a gangrenous condition. Free stimuli and nutritious broths were ordered.

May 4th.—The patient is in a somewhat better condition; the tongue is moister; the pulse is still about 100, small and feeble; the slough is separating from the wound; and less fecal matter comes away by the artificial anus. The patient takes her nourishment well, which consists of fish, beef tea, and wine.

7th.—Slough has entirely separated from the wound, which is beginning to granulate; pulse still continues small and weak; tongue moister and cleaner; very little fecal matter comes away by the wound, most of it coming through the natural passage.—Ordered wine freely, and a mutton chop.

10th.—Patient doing well; the wound is granulating in a healthy manner, but still a large quantity of feces come away through it.—To go on.

15th.—She has remained in a similar state since the last report, if anything, however, the patient is lower; she still lies in a sleepy condition; pulse very small; faeces somewhat dusky; she does not vomit; nearly all the fecal matter comes away by the wound. She is plentifully supplied with stimulants and nutritious food.

25th.—This old woman still continues in a curious condition: since the last report, she has fluctuated much; at different intervals she has been very low, and as though she were about to sink, but during the last few days she has improved, her countenance has become more cheerful, her tongue cleaner, and she has taken her nourishment well. As the faeces came almost entirely from the wound, and the opening in the intestine, which was at

the upper part of the wound, appeared to be valvular, Mr. Bowman applied careful pressure on the upper part of the artificial orifice, and this appeared to act with efficacy for two or three days, as less fecal matter came away; but at the end of this time vomiting occurred, and it was found necessary to omit the pressure. Now, however, much less comes by the wound, and the patient has motions "per vias naturales." She is supported by a large quantity of stimuli and fluid nourishment.

June 1st.—Since the last report matters have taken an unfavourable turn with the patient: she gradually began to sink, although no symptoms of any inflammatory mischief presented themselves; the pulse continued feeble, varying from 90 to 100; the tongue remained slightly furred and dry; vomiting occurred at intervals; some of the faeces continued coming through the opening, and some by the rectum. She was supported by a liberal amount of stimuli, but she gradually got worse, and died on the 31st of May.

On making a post-mortem examination, nothing particular was found which could account for death. There was some slight effusion of lymph on the peritoneal surface of the intestines. On looking at the parts from within, it was found that a complete artificial anus had been formed, and so effectually as to prevent the effusion of matters into the peritoneal cavity; the portion of the small intestine which had been opened by ulceration was firmly attached by adhesive matter to the circumference of the opening.

This case must be looked upon as one of extreme interest, both to the practical surgeon and pathologist, for it was here shown by the post-mortem examination how well nature's efforts had succeeded both in remedying an accident which had occurred after the operation, and in preventing the disastrous results which would have ensued from the escape of the contents of the intestine into the general cavity of the peritoneum. A complete artificial anus had been formed, and the intestine was so firmly and closely adherent on all sides to the opening on the inner surface of the abdominal wall, that no escape of fecal matter into the cavity could take place.

Herein was beautifully shown how well nature works in such instances; and had there been sufficient strength of constitution in this patient, the ultimate result would, in all probability, have been favourable: but, unfortunately, the subject was old, and exceedingly fat, which condition of things is at all times unfavourable to the success of a severe operation.

It is somewhat interesting to ascertain

how it was that the intestine should have become perforated in this instance; for, as it was mentioned in the former report, that portion of the gut which was found lying in the sac at the time of the operation, although it was highly congested and dark as chocolate, did not present any features of gangrene. The cause of the subsequent gangrene, in all probability, arose from without, for it was seen that sloughing had attacked the hernial sac lying in the wound, and then a portion of the intestine was discovered to be in an equally diseased condition. Most probably the sloughing had extended from one to the other—the sac first, and afterwards the gut.

In our report of the same date, we mentioned a case of impermeable stricture of the urethra complicated with stone, for which Mr. Fergusson operated: we shall now continue the history of this interesting case up to the present time. For a few days after the operation this patient seemed to improve very much, the urine came freely away from the opening in the perineum, and much less from the sinus in the abdominal wall, and his appetite increased; but about a week after this proceeding, the patient began to go back, and he was seized with vomiting, became jaundiced, and had some hæmorrhage from the gums; he also complained of considerable pain in the abdomen, particularly on the right side, which was very tender on pressure, and on examination the liver was found to be enlarged and painful. Calomel and opium was ordered, and hot fomentations were applied over the abdomen, which gave the patient considerable relief.

May 2d, twelve days after the operation. —His countenance is somewhat anxious; he vomits occasionally; and complains of considerable pain over the abdomen, more particularly when the region of the liver is pressed; pulse 100, feeble, but irritable; countenance still slightly tinged, but not so jaundiced as it was. Dr. Todd saw this patient to-day, and ordered one grain of opium to be taken three times a-day, and hot fomentations, with laudanum, to be applied over the abdomen; fluid nourishment to be taken.

4th.—Feels and looks much better; the opiate treatment has given very great relief; there is now no jaundice, and the countenance is much more cheerful; tongue clean; pulse 100, still very irritable. As he has been so ill, Mr. Fergusson has not meddled with the wound, and has not attempted to pass any catheter. The urine still comes freely away by the wound, and he is much less disturbed than he used to be by the irritability of his bladder.

7th.—Improving; has not much pain in

the belly; liver is still large and somewhat painful; countenance much clearer and more cheerful; tongue clean; pulse 100; urine still keeps coming freely away through the wound. Takes some wine, and nourishing broths, &c.

10th.—Still doing well. Mr. Fergusson attempted to-day to pass a small catheter through the strictured portion of the urethra, which involves the greater portion of the corpus spongiosum, but it was perfectly impermeable to the catheter.—Potassa Fusa was therefore applied to the face of the stricture.

15th.—The Potassa Fusa has been again applied, but no instrument whatever can be carried through the strictured portion of the canal. The urine still comes freely away by the hernial opening, and a large gum catheter can be easily passed through it into the bladder. Very little water comes from the sinus in the abdominal walls. The patient, although much better than he has been, still is very weak.

May 25th.—This patient has lately been improving so much, that he is enabled now to get out of bed, and put his clothes on. He feels very much the benefit of the operation which has been performed upon him: the urine comes away freely by the perineal opening, which has been kept in free communication with the bladder by the passage from time to time of a short elastic catheter: there is comparatively little irritability of the bladder. Still, however, little progress has been made with the stricture in front of the opening: it is so long and tough, that the Potassa Fusa appears to have made scarcely any impression upon it, as no instrument whatsoever could be got down. The general health is much improved, although it continues in a weak condition.

29th.—Mr. Fergusson, at his visit to-day, made a very careful and patient attempt to get a small wire through the stricture, but although after a long trial he was enabled to get some way into the stricture apparently, he could get nothing through it. He therefore divided it from within by an instrument of his own invention, consisting of a long director, with a deep groove in it, and a long narrow knife, with a cutting edge at its extremity, of about one inch in length. He first passed the director down to the stricture, and then passed the knife into the groove, which is so deep that the cutting edge of the knife does not come into contact with the healthy urethra, but only cuts the stricture. He was enabled by this means freely to divide it on either side. An attempt was now made to pass a catheter, but it was not successful.

June 1.—Mr. Fergusson was able, at his visit on the 29th, to pass with some little

difficulty a No. 2 catheter fairly along the urethra, into the bladder, and to-day he passed, without difficulty, a No. 4, and the patient has suffered but little from the cutting operation lately performed.

We shall continue the report at a future time of this extremely interesting case.

In a former report we related an instance in which the Taliaacotian operation had been performed on a young man by Mr. Fergusson; at that time the first steps only of the operation had been done,—that is to say, the integument of the forehead had been detached, and drawn over the old nose.

Almost complete union took place on either side, where the raw surfaces were in apposition; but unfortunately the patient was seized with a most severe attack of erysipelas, whereby his life was placed in imminent danger. The symptoms were so severe a few days after the commencement of the attack, that it was deemed necessary to apply restraint: the man became violently delirious, and remained in a state much resembling acute mania, for several days; in this state he was removed to the physician's hands, where Dr. Todd saw him, and under his superintendence the patient gradually recovered. His nose was in great danger of being pulled off during the maniacal attacks under which he suffered, but he was carefully watched and restrained, and fortunately the union of the wounds was not prevented.

He was permitted to go out for some weeks to recruit his health; he returned at the beginning of last month, and on examination there was found to be a very firm union of the new nose, on either side, with the exception of a small portion near the apex; Mr. Fergusson therefore carefully pared the edges, and having separated the narrow connection of the nose to the skin of the forehead he brought them accurately together by sutures. The patient, fortunately, has not suffered from any erysipelatous attack this time; perfect union of the whole of the new nose with the face has taken place, and the patient altogether makes a very respectable appearance, and certainly is a much less disagreeable object than he was before the operation was done upon him. It is remarkable to observe how little disfigurement there is on the forehead, for although a very large raw surface was left after the first operation, the parts have cicatrised so well, that very little is there to be seen, and this little the patient will be able to cover with his hair.

Medical Intelligence.

THE CHOLERA ON THE CONTINENT.

Vienna and Venice.—This disease has recently made its appearance at Vienna and in Venice, and has occasioned numerous deaths.

Prague.—Accounts from Prague of the 26th June, state that the cholera has been very severe in that city during the last three weeks. From the 16th to the 23d June there were 57 cases, of which 28 proved fatal.

Algiers.—The cholera has reappeared on the northern coast of Africa. It destroyed in one day, at Tunis, 150 persons.

Malta.—Letters from Malta of the 2d inst. state that there is now no doubt of the cholera being in the island. Several cases occurred on board the fleet, some of which proved fatal. Among the troops the disease was confined to the 44th Regiment, quartered in the low, ill-aired buildings at Florian. There were, exclusive of the men of both services, 39 cases and 34 deaths in the city. A postscript, written at post hour, mentions the total number of cases among all classes at 82, and deaths 60. Cholera, though not of a dangerous character, was raging among the children.

London.—In the Registrar-General's return for the week just completed, there is an account of one death from (English) cholera. This was the case of a boy of seven years residing in Lambeth. The disease proved fatal in fourteen hours.

ALLEGED PROTECTIVE POWER OF SYPHILIS AGAINST CHOLERA.

M. PROVENCAL, of Montpellier, has addressed a communication to the President of the Republic, claiming the honour of the discovery of the immunity of venereal patients from cholera, owing to the protective power of the syphilitic poison. The same physician proposed the inoculation with syphilitic poison, and demanded a national recompense for the said discovery.

The President of the Academy, M. Velpeau, however, and several other members, stated that they had seen many syphilitic patients die from cholera. So that the protective power of syphilitic virus, or of the therapeutic mercurial action, does not exist. The practice has been officially reprobated and authoritatively forbidden.—*L'Union Médicale.* X

MILLBANK PRISON — STATISTICS OF MORTALITY, &c., FOR 1849-50.

THE recently printed report on this prison

announces that it is intended that about 700 cells shall be used for the detention of prisoners passing their probationary period in separate confinement previously to being sent to penal labour or public works, but the period of separate confinement in Millbank, owing to its peculiar local circumstances and the unfavourable influence they exercise on the health of the inmates, will not generally be continued beyond eight or nine months, instead of twelve months, which is fixed as the period of detention at Pentonville and other prisons of that class. The number of convicts in the prison on the 1st of January, 1849, was 1,144 (1,058 men and 86 women), and on the 1st of January last, 1,093 (955 men and 138 women). The deaths in the year were 94, or 8·2 per cent. The expenses of the establishment were £31,821. 18s. 8d., and the net amount of profit by prisoners' earnings in the year £3,760. 15s. 6½d. The smallness of the earnings arose from the breaking up of the establishment on account of the cholera which prevailed last year.

GREAT MORTALITY FROM FEVER, AT RIO JANEIRO.

ACCORDING to the latest intelligence from Rio Janeiro, we learn that the fever had somewhat abated on shore, but amongst the shipping it still continued its ravages: 14,000 of the inhabitants are reported to have fallen since January, out of which about 120 are English residents and 150 British seamen, including 8 masters and 18 mates of merchant ships; a still greater mortality occurred amongst the foreign shipping. Her Majesty's ship Tweed had lost 18 officers and seamen; Her Majesty's steamer Comorant, 12 officers and seamen; the Portuguese ship-of-war Vasco de Gama had lost 150 of her officers and crew; and the constitutional Brazilian frigate, 100 officers and men. At Bahia and Pernambuco the fever still continued, but not with such virulence.

OBSTETRICS IN SPAIN.

ONE of the leading journals of the Spanish capital has the following extraordinary announcement regarding the expected delivery of the Queen of Spain. It has evidently been penned by a *lunatic*. It is to the effect that "the delivery will probably take place this week. As the moon is well known to exercise an influence over such events, the confinement of Her Majesty is generally expected, either on Tuesday, the 2nd, or on the 9th, the day of the new moon."

. It is our belief, that the moon has no such influence in the British empire!

STATISTICS OF THE POPULATION OF PARIS.

In 1848 there were in the city of Paris—

Births	32091
Deaths	30088

Excess of deaths over births 2003

Births.

Males	16028
Females	15968

Excess of males over females 955

Of the births there were—

Legitimate children (born in wedlock)	22068
Illegitimate (born out of wedlock)	10823

Deaths.

Males	15822
Females	14266

Excess of deaths of males 1556

Of these, 564 bodies were exposed at the Morgue,—namely, 51 females, and 513 males.

HONOURS CONFERRED ON DR. HASTINGS AND CARSWELL.

AT the levee held on the 3d instant, Her Majesty conferred the honour of knighthood on Dr. Hastings, of Worcester, well known as the founder and President of the Provincial Association; and on Dr. Carswell, formerly Professor of Pathological Anatomy in University College, and now Physician to Leopold, King of the Belgians. Such honours are so rarely conferred in this country on medical men, or men of science, that this is an event which deserves to be recorded. There are some other professional men whom we could name, who, by the distinguished position which they have won for themselves in the ranks of the profession, are deserving of the honour of a baronetcy, or of knighthood.

VIOLENT CRAMPS CAUSED BY GREEN TEA.

A YOUNG man, twenty-eight years of age, of intemperate habits, took one evening, after being fatigued, as much as a quart of strong green tea, which he drank in cups one after the other. After several hours of disturbed sleep, his skin was covered with a profuse perspiration, and he exhibited symptoms of congestion of the brain. His pulse was frequent, but soft. Suddenly severe and fearful paroxysms of general convulsions, and tonic cramps, occurred. Consciousness was lost; the patient tossed about, tore his bedding, and gnashed his teeth. Opisthotonos, emprosthotonos, and trismus, alternated. Scarcely did one paroxysm subside before another followed. This state lasted three days, and was succeeded by a long and severe attack of delirium tremens, from which, however, he recovered. —*Casper's Wochenschrift.*

THE GLASGOW FACULTY.

An Act for better regulating the Privileges of the Faculty of Physicians and Surgeons of Glasgow, and amending their Charter of Incorporation. 13 Vic. c. 20.

WHEREAS the Faculty of Physicians and Surgeons of Glasgow were incorporated by royal charter granted by His Majesty King James the Sixth of Scotland, under the Privy Seal of that kingdom, on the twenty-ninth day of November, one thousand five hundred and ninety-nine, which Charter was ratified by an act of the Scottish Parliament passed upon the eleventh day of September, one thousand six hundred and seventy-two. And whereas by the said Charter the said Faculty were empowered to call before them and examine all persons practising surgery within the city of Glasgow, and the counties of Lanark, Renfrew, Dumbarton, and Ayr; to admit and grant licenses to such of the said persons as they should find qualified; and to debar all others from exercising the profession of surgery within the limits aforesaid; which powers the said Faculty have from the date of the said Charter exercised, and still enjoy. And whereas the city of Glasgow, and the said counties of Lanark, Renfrew, Dumbarton, and Ayr, over which the privileges of the said Faculty extend, comprehend a populous, wealthy, and important district of Scotland. And whereas it would be of advantage to the public, and also to the medical profession, if the exclusive privileges enjoyed by the said Faculty were so relaxed and amended that all persons found qualified and licensed to practise surgery by any corporation authorised by law to grant such licenses might have right to practise within the said district, and the right of all persons found qualified and licensed by the said Faculty to practise beyond the said limits were better defined, and if the members of the said Faculty were hereafter designated "Fellows of the Faculty of Physicians and Surgeons of Glasgow." And whereas the said Faculty have raised and established a fund of provision for the widows and children of the members thereof, and it has hitherto been considered obligatory upon all persons becoming Members of the said Faculty to become also contributors to the said fund; and it is expedient that such obligations should cease; but these objects cannot be effected without the authority of Parliament. May it therefore please Your Majesty that it may be enacted; and be it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, that the present Members of the said

Faculty of Physicians and Surgeons of Glasgow, and such persons as shall be hereafter admitted into the said corporation, shall be known by the name and style of "Fellows" thereof; and shall, except in so far as hereby otherwise provided, possess, exercise, and enjoy the same powers and privileges as those heretofore possessed, exercised, and enjoyed by the Members of the said Faculty.

II. And be it enacted, that the Fellows and Licentiates of the said Faculty shall respectively enjoy the same status and privileges in the practice of their profession, and be equally eligible to the same offices in connection therewith, throughout Her Majesty's dominions, as if the said Faculty had been specially authorised by law to grant licenses or diplomas in surgery conferring the same status and privileges as those conferred by any other corporation or royal College in Scotland which now is or may hereafter be authorised by law to grant such licenses or diplomas: provided always that nothing herein contained or authorised shall interfere with any exclusive privileges heretofore granted by competent authority to any other corporation or royal College, so far and so long as such exclusive privileges remain in force and unrepealed.

III. And be it enacted, that the Fellows and Members, or Licentiates, respectively, of any other corporation or royal College which now is or hereafter may be authorised by law to grant licenses or diplomas in surgery, shall, within the city of Glasgow, and counties of Lanark, Renfrew, Dumbarton, and Ayr, enjoy the same status and privileges in the practice of their profession, and be equally eligible to the same offices in connection therewith, as the Fellows and Licentiates respectively of the Faculty of Physicians and Surgeons of Glasgow.

IV. And be it enacted, that no person who shall hereafter be admitted a Fellow of the Faculty of Physicians and Surgeons of Glasgow shall be obliged to become a contributor to the fund raised and established by the said Faculty for the widows and children of the Members thereof as aforesaid; nor shall any such person, or the widow or children of any such person, have any interest in the said fund, unless such person shall voluntarily become a contributor thereto, according to the regulations thereof in force for the time being.

V. And be it enacted, that neither the Faculty of Physicians and Surgeons of Glasgow, nor its office-bearers, nor the Fellows of the said Faculty, in consequence of their admission into the said corporation, shall have any claim to or interest in any part of the said fund, as presently vested in or under the management of the trustees

thereof or contributors thereto; but the same shall remain the sole property, and be under the exclusive management and control, of the contributors to and trustees of the said fund for the time being; and the said trustees shall have full power to demand, sue for, uplift, and discharge all sums owing to or invested for behoof of the said fund, without the interference or concurrence of the said Faculty, or its office-bearers or Fellows, and to manage, and from time to time to re-invest the same in the name of the trustees for the time being of the said fund, for behoof thereof.

VI. And be it enacted, that nothing herein contained shall prevent the Faculty of Physicians and Surgeons of Glasgow from altering the rules and regulations heretofore made by the said Faculty under the powers contained in the said Charter, or from making such new rules and regulations as may be necessary for carrying into effect the purposes of the said Charter and of this act; provided always that such new or altered rules and regulations shall not be inconsistent with this act or with the laws of the realm.

VII. And be it enacted, that this act shall commence and take effect from and after the passing thereof.

VIII. And be it enacted, that this act shall be a public act, and shall be judicially taken notice of as such.

CASE OF THE LATE SIR R. PEEL.

It was ascertained, on a slight examination, that there was a comminuted fracture of the left clavicle. Our contemporary, the *Lancet*, states that a swelling as large as the hand was subsequently formed below the fractured clavicle, which pulsed to the touch synchronously with the action of the heart. When examined carefully by the eye, it was found that the movement of this tumor corresponded with the contractions of the auricle, and was, in some respects, similar to the pulsations observed in the veins of the neck in very thin persons, and in certain forms of venous regurgitation. It was evident, from these signs, that some vein beneath the clavicle, probably the subclavian, had been wounded by the broken bone at the time of the fall; and that the subclavicular swelling consisted of blood effused from the wounded vessel. It was also evident that the swelling was in this way connected with the heart, forming what might be called a diffused false venous aneurism. The severe pain suffered by the deceased has been attributed to the rupture of some nerves connected with the axillary plexus. It might be accounted for, however, by the fractured rib (an accident discovered after death), and the general concussion pro-

duced by the fall. This must have been very severe in order to have produced a comminuted fracture of the clavicle. It is not improbable that there was injury to some of the internal organs. We are informed that there was complete suppression of urine during the two days which the deceased survived.

There is no ground whatever for supposing that Sir Robert fell from his horse owing to a sudden epileptic attack. All the facts concur to prove that the fall was the result of accident.

CAUSE OF THE GREEN COLOUR OF THE WATER OF THE SERPENTINE.

At a recent meeting of the Botanical Society of London, Dr. A. Hassall read a paper on this subject. In this communication it was shown that the periodical and coppery-green colouration of the water of the Serpentine is due to the presence of a minute plant belonging to the tribe of *Algae*, of which the writer gave a detailed and critical description, and which he named *Thompsoni*. The development of this plant takes place early in the spring, out of sight and at the bottom of the water, and it is only on the approach of the warm weather of summer that it diffuses itself through the water, deeply colouring it, and that part of it rises to the surface, forming a scum or pellicle of a bright æruginous or coppery-green colour. The whole of the water of the Serpentine is not usually coloured at one time, but different portions of it at different times, according to the strength and direction of the wind, which drives the plant before it. At one time it is found to collect at the Hyde Park extremity; at another it is present in the Kensington division; sometimes in the north and at others on the south shore—the remaining parts of the Serpentine being entirely free from the plant. This variable distribution which, unexplained, would be apt to occasion surprise, accounts for the fact that the observer may sometimes visit the Serpentine and not see a trace of the plant in question; and hence he might be led to form an erroneous conclusion as to the condition of the water. The observer, therefore, who wishes to come at its real state, should make the tour of the whole of the Serpentine. Considered in a sanitary point of view, Dr. Hassall is of opinion that the plant, when actually introduced into the system, as when swallowed in bathing, would not be productive of effects injurious to health, and regards it as a test of impurity and as an evidence of the very bad condition in which the water of the Serpentine now undoubtedly is. Dr. Hassall concluded the communication by observing that the colouration of large pieces of water by means of conferva is by no means un-

frequent, and cited as a remarkable instance of it the Red Sea, which derives its name and colour from the presence of a minute plant diffused through the water of a blood-red colour.

With due deference to the learned lecturer, the Red Sea is commonly considered to derive its name from "Edom, which signifies 'red.'" It was formerly called the sea of Edom. Travellers who have sailed down this Sea have assured us that there is nothing red about it.

THE MEDICAL PROFESSION AND PAWNBROKERS.

It is not commonly known that the three gilt balls displayed by pawnbrokers as a sign of their craft, are three gilt boluses, the heraldic distinction of the celebrated Medici family of Florence.

The founder of the Medici family was of the medical profession, and probably took his name from this, as the progenitors of the Smiths, Coopers, Bakers, and Turners of our own country took their names from their respective trades. The first members of the Medici family added to their gains by usury: they thus acquired wealth, and rose to distinction. They subsequently threw off the profession, but the family escutcheon retained the boluses; and this symbol of usury and money-lending is now considered an indispensable sign of the pawnbroker's trade.

IRISH LUNATIC ASYLUMS.

ACCORDING to a return to Parliament (just issued) there are 329 governors of lunatic asylums in Ireland. There are 426 officers and servants belonging to the district lunatic asylums, whose annual pay amounts to £8,994. 17s. 9d. In three years, ending the 31st December last, there were 674 urgent cases admitted. The total number of patients in the period was 7,320: the number of curable cases was 2,938, and of incurable cases 4,382.

ROYAL FREE HOSPITAL.

At the quarterly meeting of the governors of the Royal Free Hospital, on the 10th inst., the report stated that during the previous three months 183 in-patients, and 6889 out-patients, had been relieved. Regret was expressed that one of the large wards, containing fifty beds, was still unavoidably closed from want of funds.

DERBY COUNTY ASYLUM.

DR. HITCHMAN, of the Hanwell Lunatic Asylum, has just been appointed Superintendent Physician of the newly erected Derby County Asylum.

PROFESSORSHIP OF SURGERY AT UNIVERSITY COLLEGE.

THE Council of University College have conferred the office of Professor of Sur-

gery and Surgeon to the Hospital, rendered vacant by the resignation of Mr. Arnott, on Mr. J. E. Erichsen, assistant-surgeon to the hospital.

ELECTION OF FELLOWS AT THE ROYAL COLLEGE OF PHYSICIANS.

THE following gentlemen have been recently elected Fellows:—Dr. Basham, Dr. Peacock, Dr. Herbert Davies, Dr. G. Johnson, Dr. Acland (Oxford), and Dr. Ormerod. The censors chosen for the year are—Dr. Mayo, Dr. Barker, Dr. Barlow, and Dr. Jeaffreson.

ROYAL COLLEGE OF PHYSICIANS—LICENTIATES ADMITTED JUNE 1880.

At the last quarterly examination held at the Royal College of Physicians, the following gentlemen were admitted licentiates:—Drs. John Anthony, Spencer Pratt, Tyler Smith, John Snow, and William Wood.

COLLEGE OF SURGEONS—ELECTION OF MEMBERS OF COUNCIL.

THE annual election of members of the Council of this institution took place on the 4th inst., in the theatre of the College, when a large assemblage of Fellows attended from all parts of the country, for the purpose of electing from among their own body three gentlemen to the vacant seats in the Council, occasioned respectively by the death of Mr. Andrews, the resignation of Mr. Grainger, and the retirement in rotation of Mr. Pilcher. The President having taken the chair, delivered an address to the Fellows on the importance of electing only those gentlemen who were calculated to uphold the honour and dignity of the institution. The election was by ballot; at its conclusion the President, Professor Joseph Henry Green, declared that Messrs. George Pilcher, Gilbert Wakefield Mackmurdo, and Francis Kiernan, were duly elected members of the Council. The votes were distributed as follows:—

	Ayes.	Noes.
Mr. Pilcher . . .	74	61
Mr. Mackmurdo . .	107	16
Mr. Kiernan . . .	106	15

Messrs. Percy and Simpson were first nominated, according to the College regulations, in place of Messrs. Mackmurdo and Kiernan. The votes were as follows:—

	Ayes.	Noes.
Mr. Percy . . .	60	73
Mr. Simpson . . .	25	108

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 28th ult.:—B. J. Wetherell—S. Beswick—J. Furse—G. F. A. Drew—J. Marsh—R. D. Kidd—J. H. Parkinson—J. G. Kent—C. E. Playfair—E. M'Sorley—T. Hardinge—C. R. Thompson—C. Purdey.

Admitted on the 5th inst.:—H. Madge—J. H. Trounce—H. H. Massey—W.

Adams—G. Pound—R. Fowler—A. Forster—J. Y. Bown—R. McCormick—G. W. New—R. Neale—J. R. Reynolds.

Admitted on the 9th inst.:—C. Warden—J. H. Seville—T. L. B. Barwis—T. H. S. Pullin—H. Manley—H. E. Fox—H. T. Cornelius—J. Higgs—C. W. Hammond—T. Clarke—E. J. Blyth.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 4th July, 1850:—Thomas Clarke, Bradford, Yorkshire—John Craven, Dockroyd, Keighley, Yorkshire—David Grant McPherson, Bristol.

OBITUARY.

On the 4th inst., at Charing, Kent, after an active and useful life, respected by all who knew him, Thomas Prescott Wilks, Esq., surgeon, in the 79th year of his age.

PREVENTION OF PHTHISIS.

ONE of the most important means of preventing the development of phthisis is the free admission of air into dwellings. Our state governments should prohibit the erection of buildings that do not meet the requirements for the maintenance of a healthy race of operatives. Not only their own interests, but those of other classes, reacted upon by them, demand such a prohibition. It has been recommended that those of the poor who marry—and the same advice might be given to others—should select habitations that contain apartments which are large, and to which the air has free access. A vigorous offspring cannot be had by unhealthy parents. The progeny may be numerous, but will be unhealthy. The early marriages in this country are a great evil. The mother, for the most part with a fragile constitution, is worn out by numerous births; and, by the care and attention given to the children, becomes a mere drudge. In society she is rarely seen, and her influence is unfelt—she too often in a few years exhibits the marks of premature old age.—*Dr. Hallowell*, in *American Journal of Medical Sciences*, Jan. 1850.

BOOKS & PERIODICALS RECEIVED FOR REVIEW.

Cases of the Cure of Consumption and Indigestion. By G. Galvert Holland, M.D. Eighteenth Annual Report of the Trustees of the Perkins Institution and Massachusetts Asylum for the Blind.

Second Report on Idiocy. By Dr. S. G. Howe, Massachusetts.

Gout: its Causes, Cure, and Prevention, &c. By Abraham Toulmin, M.D.

Boston Medical and Surgical Journal. June 1850.

Parish Maps, and other Matters. By C. R. Walsh, M.R.C.S.

Comparative View of the different Anæsthetic Agents. By G. Hayward, M.D. Comptes Rendus. Nos. 24 and 25; 17 and 20 June.

The Chrono-Thermalist. No. 5; July.

BIRTHS & DEATHS IN THE METROPOLIS

During the Week ending Saturday, July 6.

BIRTHS.	DEATHS.
Males... 640	Males... 406
Females... 607	Females... 388
1847	794

CAUSES OF DEATH.

ALL CAUSES	794
SPECIFIED CAUSES	791
1. Zymotic (or Epidemic, Endemic, Contagious) Diseases...	169
<i>Sporadic Diseases, viz.:</i>	
1. Dropsy, Cancer, &c.	38
2. Brain, Spinal Marrow, Nerves, and Senses	112
4. Heart and Bloodvessels	38
5. Lungs and organs of Respiration	70
6. Stomach, Liver, &c.	37
7. Diseases of the Kidneys, &c.	9
8. Childbirth, Diseases of Uterus, &c.	8
9. Rheumatism, Diseases of Bones, Joints, &c.	10
10. Skin	6
11. Old Age	30
12. Sudden Deaths	7
13. Violence, Privation, Cold, &c.	25

The following is a selection of the numbers of Deaths from the most important special causes.

Small-pox	6	Convulsions	38
Measles	17	Bronchitis	31
Scarlatina	20	Pneumonia	28
Hooping-cough	28	Phthisis	121
Diarrhoea	40	Lungs	2
Cholera	1	Teething	7
Typhus	35	Stomach	3
Dropsy	12	Liver	11
Hydrocephalus	25	Childbirth	6
Apoplexy	20	Uterus	2
Paralysis	19		

REMARKS.—The total number of deaths was 83 below the average mortality of the twenty-seventh week of ten previous years. The only circumstance calling for notice is the progressive increase of deaths from diarrhoea. The deaths from this cause were 40, while the decennial weekly average is 24.

METEOROLOGICAL SUMMARY.

Mean Height of the Barometer 29.78
 Thermometer 59.6
 Self-registering do. Max. 85.2 Min. 37.
 * From 12 observations daily. * Sun.

RAIN, in inches, 0.72.—Sum of the daily observations taken at 9 o'clock.

METEOROLOGICAL.—The mean temperature of the week was 1° above the mean of the month.

NOTICES TO CORRESPONDENTS.

Communications have been received from Dr. Robinson, Newcastle; Dr. Pearson; Mr. Rose; Mr. Jennette; Dr. J. C. Warren, U.S.; Mr. Galloway; and Dr. Barclay.

The papers of Mr. Marson, Mr. Smith, and Mr. Moore, next week.

We are again compelled to postpone Mr. Harvey's Obstetric Cases. They will be published in the following number.

Lectures.

LECTURES
ON INFLAMMATION,
(Delivered in the Theatre of the Royal
College of Surgeons of England).

BY JAMES PAGET,
Professor of Anatomy and Surgery to the
College.

LECTURE VI.

Nature and Causes of Inflammation. Limitation of the term 'increased action' as applied to the process of inflammation. Indications of defective nutrition, and defective exercise of the vital forces; in the effects described in the preceding lecture, and in the low organic characters of the inflammatory products, and in the conditions preceding the process. Peculiarities by which the inflammatory mode of nutrition is generally distinguished from hypertrophy, atrophy, and the production of new growths, such as tumors.

Proximate causes of inflammation traced to qualitative changes of the necessary conditions of normal nutrition; as, 1. of the Blood-vessels: 2. of the Blood; especially inoculable diseases, and specific inflammations; explanation of the localization of a general disease of the blood: 3. of the Nervous force, as affecting the size of the blood-vessels, and as having a share in the plastic forces: 4. of the proper tissues of the inflamed part.

An examination of the nature of the process of inflammation may best be made in the form of a comparison of its effects with those of the normal process of nutrition. And this comparison may be drawn with two principal views; namely, to determine, 1st—how the effects of inflammation differ, in respect of quantity, from those of the normal process; and 2nd, how they differ from the same, in respect of quality or method.

The decision on the first of these points may seem to be given in the term 'increased action,' which is commonly used, as synonymous with inflammation. As used by Mr. Hunter, this term was meant to imply that the small vessels of an inflamed part are more than naturally active, in formation or absorption, or in both these processes. This is, probably, the meaning

still generally attached to the term by some; while, as employed by those who believe the vessels are only accessories in the work of nutrition, the expression 'increased action' may be used to imply merely increased formation, or increased absorption. In either, or in any, meaning, however, the term seems to involve the idea of an increased exercise of the vital forces, i. e. of those forces through the operation of which the various acts of organic formation are accomplished. But, if 'increased action' is to imply this, the description of the process and effects of inflammation shows that the term cannot be properly used, without some limit or qualification.

If we consider the quantity of organic formation effected during the inflammatory process, in the proper substance of the inflamed part, it is evidently diminished. All the changes described in the last lecture are signs or results of diminished or suspended nutrition in the tissues of the inflamed part: they are all characteristic of atrophy, degeneration, or death. The tissues become soft or quite disorganized; they are relaxed and weakened; they degenerate, and remain lowered at once in structure, chemical composition, and functional power; or else, after degeneration, they are absorbed, or are disintegrated, or dissolved, and cast out; they die in particles or in the mass. During all the process of inflammation, there is no such thing as an increased formation of the natural structures of the inflamed part; they are not even maintained; their nutrition is always impaired, or quite suspended. It is only after the inflammation has ceased that there is an appearance of increased formation in some of the lowly organised tissues, as the bones and cellular tissue.

So far, then, as the proper substance of the inflamed part is concerned, there appears to be decreased action; that is, decreased formation. There may be, indeed, an increased absorption; but this is also, in one sense, characteristic of decreased exercise of vital force; since all absorption implies a previous degeneration of the part absorbed. Nor can we justly call this, in any sense, 'increased action,' till we can show how absorption is an act of vessels.

On the whole then, we may conclude, thus far, that one of the constituents of the inflammatory process, one of the characters in which it differs, in respect of quantity, from normal nutrition, is a defect in the nutrition of the proper substance of the inflamed part.*

* This has been clearly maintained by Dr. Carpenter. See Br. and For. Med. Rev. July, 1844.

But it is characteristic of inflammation, that, while the inflamed part itself suffers deterioration, there is a production of material which may be organized. Here, therefore, may be an evidence of increased formation, of increased action.

Doubtless, in relation to the productive part of the inflammatory process, the expression 'increased action' may be in some sense justly used; for the weight of an inflamed part, or of the material separated from it, may be much increased by the formation of organized matter. But the quantity of organized matter formed in an inflammation must not be unconditionally taken as the measure of increase in the exercise of the vital forces: for it is to be observed, that the material formed presents only the lowest grades of organization, and that it is not capable of development, but rather tends to degeneration, so long as the inflammation lasts.

It may be but a vague estimate that we can make of the amount of vital force exercised in any act of formation; yet we may be sure that a comparatively small amount is sufficient for the production of low organisms, such as are the fibrinous and corpuscular lymphs of inflammation. The abundant production of lowly organised structures is one of the features of the life of the lowest creatures, in both the vegetable and animal kingdoms. And, in our own cases, a corresponding abundant production is often noticed in the lowest states of vital force; witness the final inflammations, so frequent in the last stages of granular degeneration of the kidneys, of phthisis, of cancer, and other exhausting diseases. In all these, even large quantities of the lowly organised cells of inflammatory lymph may be formed, when life is at its last ebb. And with these cases correspond those that show the most rapid increase of tubercle and cancer, and other lowly organised tumors, when the health is most enfeebled, and when the blood and all the natural structures are wasting.

From these considerations, we may conclude that the productive part of the inflammatory process is not declaratory of the exercise of a large amount of vital, or organising, force; and this conclusion is confirmed by observing that development, which always requires the highest and most favoured exercise of the powers of organic life, does not occur while inflammation lasts. The general conclusions, therefore, may be, as well from the productive, as from the destructive, effects of the inflammatory process, that it is accomplished with small expenditure of vital force, and that even when large quantities of lymph are formed, such an expression as "increased action" cannot be safely used, unless we can be sure that the

defect of the formative power exercised in the proper tissue of the inflamed part is more than counterbalanced by the excess of power manifested in the production and low organisation of lymph.

It may be said that the signs of inflammation are signs of increased action. But these are fallacious, if, again, by increased action be meant any increased exercise of vital force. The redness and the swelling of an inflamed part declare the presence of more blood; but this blood moves slowly; and it is a quick renewal of blood, rather than a large quantity at any time in a part, that is significant of active life. An abundance of blood, with slow movement of it, is in no case characteristic of activity in a part; it more often implies the contrary, as in the erectile tissues, and the cancellous tissue of bones.

The sign of heat in the inflamed part is equally fallacious. The source of the locally increased heat cannot, I believe, be satisfactorily explained. This phenomenon of inflammation is involved in the same difficulty as are all those that concern the local variations of temperature in the body: difficulties which the doctrines of Liebig, however good for the general production of heat, are quite unable to explain. But, from the fact that the general supply of heat in our bodies is derived from oxydation or combustion of wasted tissues or of surplus food, we may assume that, in local augmentation of heat, the source is rather from some similar destruction of organic substances, than from increased formation of them. This can, indeed, be only assumed; but, if there be little evidence for it, there is as little for any assumption that the increased heat of an inflamed part is an indication of an increased formative action. The full heat of an actively growing part may be compared with the high temperature of one which is the seat of "determination" of blood, or of "active congestion;" for, in both cases, the heat is high because the blood, brought quickly from the heart, is quickly removed; but, in an inflamed part, the blood is not so renewed; it moves more slowly.

In thus endeavouring to estimate the difference between the normal and the inflammatory modes of nutrition, in regard to the quantity of formative or other vital force exercised in them respectively, I have also stated the chief differences between them in relation to the quality or method of nutrition. The most general peculiarity of the inflammatory method, in its simplest form, is the concurrence of these two distinct and independent, though usually coincident, events: namely, 1st, the impairment or suspension of the nutrition of the proper

substance of the inflamed part: and 2nd, the effusion, from the blood, of a material more than sufficient in quality for the nutrition of the part, but less than sufficient in its capacity of development.

The predominance of one or the other of these components is the ground of some of the chief varieties in the forms of inflammation; distinguishing, especially, the adhesive and suppurative inflammations, in which the formative part predominates, from the ulcerative and gangrenous, in which the destructive part prevails. But in all cases, the two components of the process are in certain measures combined, and their combination establishes the chief differences between the inflammatory and every other mode of nutrition in a part. Thus, from all the forms of mere atrophy or degeneration, the inflammatory process is distinguished by the production of the lymph, which may be organising, even while the proper tissue of the inflamed part is in process of atrophy, degeneration, or absorption. So far as the tissues inflamed are concerned, some inflammations might be classed with atrophies or degenerations; but the concurrent production of lymph is distinctive of them.

On the other side, the inflammatory mode of nutrition is distinguished from all the forms of hypertrophy by the failure of the nutrition of the inflamed part itself. So far as mere production and formation of organisms are concerned, some inflammations might be paralleled with hypertrophies; but the organisation of the lymph falls short of that proper to the part in which it is exuded; and the substance of the part, instead of being augmented, is only replaced by one of lower organisation.

And, lastly, from the production of new growths, such as tumors, the inflammatory process is distinguished by this;—that its organised products, though like natural tissues of the body, are usually infiltrated, fused, and interwoven into the textures of the inflamed parts; and that, when once their development is achieved, they have no tendency to increase in a greater ratio than the rest of the body.

I am well aware that these can be accepted as only the generally distinguishing characters of the simplest inflammatory process. Cases might be easily adduced in which the border-lines are obscured; inflammations confounded on one side with atrophies, on another with hypertrophies, on a third with tumors. But the same difficulties are in every department of our science; yet we must acknowledge the value of general distinctions among diseases even more alike than these are.

The case that I have chosen for illustrating the general nature of the inflammatory

process is one representing the disease in its simplest form and earliest stage, manifesting only the formation of lymph, and such a change as the softening or absorption of the inflamed part. This is but the beginning of the history; but, if the inflammation continues, or increases in severity, all that follows is consistent with this beginning; all displays the same double series of events, the same defective nutrition of the part, and the same production of low organisms. But these additions are observed; the part is more and more deteriorated, and perishes in the mass, or in minute fragments; the newly-organised products, not finding the necessary conditions of all nutrition, partake in the degenerative process, and, instead of being developed, are degenerated into pus, or some yet lower forms, or perish with the tissues in which they are imbedded.

Respecting, now, the causes of inflammation, I shall not say more of its exciting causes than that, from the external ones, which alone we can at all appreciate, we may derive a confirmation of the opinion I have expressed concerning the nature of the process. They are such as would be apt to produce depression of the vital forces in a part; all being, I think, such as, when applied with more severity, or for a longer time, will lead, not to inflammation, but to the death of the part. If a certain excess of heat will inflame, a certain yet greater heat will kill: if some violence will inflame, a greater violence will kill: if a diluted chemical agent will only irritate, the same concentrated will destroy the part. The same may be said, I think, of cold, mechanical injury, and all the other external exciting causes of inflammation. I am aware that other explanations of their action are given; but none seems to me so simple, or so consistent with the nature of the process that follows them, as this, which assumes that they all tend (as it may be said) to depress the vital forces exercised in the affected part: they may be stimulants or excitants of the sensitive nerves of the part, but they lead to the opposite of activity in its nutritive processes.

The proximate causes of inflammation appear to be various perversions of the necessary conditions of healthy nutrition in a part; that is, morbid changes in either the supply of blood, the composition of the blood, the influence of the nervous force, or the condition of the proper substance of the inflamed part. Any one or more of these four conditions of nutrition being changed in quality, the result appears to be an inflammation. A change in quantity more usually produces either an excess or deficiency of nutrition in the part, or

some process different from inflammation. Thus, a diminution or withdrawal of the blood, without alteration of its quality, is usually followed by atrophy, degeneration, or death: a mere increase of blood in a part may produce hypertrophy, or something more nearly resembling inflammation, yet falling short of it. Similar effects may ensue from a mere increase or decrease, or abstraction, of nervous force. Change in the quality, whether with or without one in the quantity, of the conditions of nutrition, appears essential to the production of the phenomena of inflammation.

I will endeavour now to show that inflammation may follow such perversion or qualitative change in each of the conditions of nutrition, even though all the rest of them remain in their normal state: selecting, for this purpose, such cases of inflammation as we may trace proceeding, in the first instance, from the uncomplicated error of a single condition of nutrition.

1st. Inflammation may perhaps be produced—it certainly may be in some measure imitated—by changes in the blood-vessels; changes attended with alteration of their size, or their permeability, or the other qualities by which they affect the supply of blood to a part. This may be concluded from the similarity to some of the phenomena of inflammation which may be observed in certain cases of mechanical obstruction to the venous circulation. In a case of ascites from diseased heart or liver, the peritoneum often contains coagula of fibrine floating free in the serum, though no organ may present appearances of having been inflamed. In such a case, moreover, I have found the fibrine developing itself in the form of nucleated blastema, even while floating free. In another case of mechanical dropsy, I have found the fluid of anasarca in the scrotum containing abundant lymph-corpuscles, like those in the fluid of an inflammatory effusion. Such as these are the cases through which mechanical congestions of blood connect themselves with inflammation. And if to these we add the constancy of increased vascularity among the phenomena of inflammation, they may be sufficient to make us believe, that disturbances in the circulation of a part may produce some of the principal phenomena of inflammation, even though all the other conditions of nutrition are, in the first instance, unchanged. But I know no other good evidence for the belief; and I think we should not lay much stress on these cases, since they display an imitation of only one part of the process of inflammation, namely, the production of organised matter. The nutrition of a part with obstructed circulation suffers but a

trivial disturbance, in comparison with that which would accompany an inflammation with an equal amount of hindrance to the movement of the blood. I should therefore be cautious of regarding these effusions in mechanical obstructions of blood as more than partial imitations of the inflammatory process. So far as the effusion in an inflammation depends on the altered mechanical relations of the blood and vessels of a part, so far may similar alterations produce effects imitating those of inflammation; but I much doubt whether any change whatever in the circulation of a part, however produced, can alone produce or alone maintain the phenomena or effects of inflammation. I believe that the disturbances of the circulation are no more adequate to the explanation of inflammation, than the normal movements of the blood are adequate to the explanation of the ordinary process of nutrition.

2. We may speak much less equivocally of the influence of the state of the blood itself in determining inflammations; for there can be little doubt that a very great majority of the so-called spontaneous or constitutional, as distinguished from traumatic, inflammations, have herein their origin. We might anticipate this from the consideration that, in normal nutrition, the principal factors are the tissues and the blood in their mutual relations: but we have better evidence than this, in cases of local inflammations occurring in consequence of general diseases of the blood. Some instances of this are clearly proved, as, *e. g.*, in the cases of eruptive fevers, when the presence of morbid materials in the blood is proved by the effects of their transference in inoculation. Scarcely less thoroughly demonstrated are the cases of rheumatism and gout, of lepra, psoriasis, herpes, eczema, erysipelas, and other such affections, whose constitutional nature—in other words, whose primary seat in the blood—all readily acknowledge in practice, if not in theory. Now, in all these cases, local inflammations are the external signs of the general affection of the blood: and I apprehend that if any difficulty be felt in receiving these as evidences that the morbid condition of the blood is the cause of the local inflammation, it will be through doubt whether a general disease of the blood—a disease affecting the blood sent to every part—can produce peculiar phenomena of disease in only certain small parts or organs. But this local effect of a general disease of blood has its illustration in some of the sure principles of physiology; especially in this—that the presence of certain materials in the blood may determine the formation of appropriate organisms, in

which they may be incorporated.* Thus, when one kidney is removed or destroyed, the other will acquire a greater size, sufficient for the discharge of the necessary quantity of urine. Now we know that the principal materials of urine exist ready-formed in the blood; that, being taken from the blood, they are incorporated in the secreting cells of the kidney, and are for a time enclosed in them, and enter into their composition; and that, finally, they are discharged into the excreting tubes from these cells, not by mere filtration. We may, therefore, safely hold that, when one kidney is lost or spoiled, more renal cells are formed in the other, *because* more of the constituents of urine are in the blood: in other words, that the presence of these constituents in the blood that is carried to every part determines the formation of appropriate organs in one part of the body; in which organs these constituents may be incorporated. Nor is this the only case. Certain medicines, especially diuretics, are separated from the blood by only certain organs; they must, for this separation, be embodied in those organs, and while embodied they may excite inflammation; as cantharides, turpentine, and the like, do. Abundant hydro-carbon principles in the blood will bring about the formation of abundant fat cells, in which they may be enclosed. The accumulation of sap in the branch of a tree that has been *ringed* will determine the organisation of abundant fruit; and many similar cases might be cited.

It is in exact parallel with these facts in physiology, that in certain general diseases of the blood, organs are formed, as the products of inflammation, within which the specific morbid material is incorporated. Thus, in small-pox, cow-pox, primary syphilis, and whatever other diseases may be transferred by inoculation, the morbid material from the blood is incorporated in the fluid and corpuscular products of inflammation, which are enclosed within the characteristic vesicle or pustule; just as, in the cases already cited, the constituents of urine or of medicines are incorporated in the renal cells, which are formed within the substance of the kidney;

* This principle was fully discussed in the Lectures on Nutrition delivered in 1847, and published in the *MEDICAL GAZETTE* of that year. And it appears to be capable of even much wider extension than was then assumed. For example, it supplies the best theoretic expression of the origin of cancerous, and similar tumors. The cells or the tissues of these growths, we may believe, are formed so as to comprise or enclose specific morbid materials generated or inserted in the blood. That each such morbid material should have, for its appropriate habitation, cells and a mass of peculiar form and appearance, is only consistent with normal rules of formation.

or just as the constituents of sap are incorporated in fruit.

In the cases of disease produced by a demonstrable virus, we have all the evidence that can be necessary to prove the principle I am contending for—namely, that a general disease of the blood may determine a local inflammation in one or more circumscribed portions of a tissue. And the analogy is so close, that I think we need not hesitate to receive the same explanation of other inflammations, which I have cited as occurring during morbid conditions of the blood. For although we cannot, by inoculation, prove that a specific morbid material of such a disease as herpes, or rheumatism, has been incorporated in the inflammatory products, yet we find great probability hereof in the many analogies which these diseases present to the inoculable diseases, in their whole history, and, especially, in the decrease of general illness which ensues on the full manifestation of the local inflammation.

If it be asked why a morbid material is determined to one part or tissue rather than another, or why, for example, the skin is the normal seat of inflammation in small-pox, the joints in rheumatism, and so on, I believe we must say that we are, on this point, in the same ignorance as we are concerning the reason why the materials of sweat are discharged at the skin, those of urine at the kidneys, of bile at the liver, or why the greater part of the fibrine is incorporated in the muscles, and of gelatine in the bones. We cannot tell why these things are so; yet we believe them, and our belief has practical advantages. So may the belief that a great majority of the so-called spontaneous local inflammations are the consequences and manifestations of certain morbid conditions of the whole mass of blood; and that when such conditions depend on the presence of any specific material in the blood, a portion, or the whole, of that material is usually incorporated in the products of the inflammation, and in them is separated from the blood.

But, again, it may be said, that if this be granted, still we need some explanation of the fact that the morbid condition of the blood does not influence the whole extent of any given tissue, but only portions of it. In the secretion of urine, it may be believed that the whole kidney is affected and works alike; but in the assumed separation of the virus of small-pox, only patches of the skin are the seats of pustules; in vaccinia and primary syphilis, only a single point; in secondary and tertiary syphilis, a certain, but often disorderly, succession of various parts, and so on.

It must be admitted that many of the facts here referred to cannot yet be ex-

plained; but such difficulty of explanation affords no warrant for a denial of the theory, especially since we are able, consistently with this theory, to point out some of the conditions that determine the locality in which a general disease of the blood will manifest itself by inflammation. In some instances, it is evident that the localisation of a general disease of the blood is determined by a previous condition, such as we may call a weakened or depressed condition—a state of already impaired nutrition—in some one part. For instance, suppose a stream of cold air is impelled on some part, say the shoulder, of a person disposed to rheumatism, it determines, as a more general exposure to cold might do in the same person, the rheumatic state of the blood, with all its general symptoms; but it determines, besides, the part in which that rheumatic state shall manifest itself first or alone. The depressed nutrition of the chilled shoulder makes it more liable than any other part to be the seat of inflammation excited by the diseased blood.

Or, again, when a virus is inserted, as in all cases of poisoned wounds, the local inflammation produced by the disease with which the whole blood is infected will commonly have its seat in the wounded part. The virus must have produced some change in the place in which it was inserted, as well as in the whole mass of the blood. These cases are, probably, only examples of the general rule, that a part whose natural force of nutrition is in any way depressed, will, more than a healthy part, be liable to become the seat of chief manifestation of a general blood-disease. Thus, a part that has been the seat of former disease or injury, and that has never recovered its vigour of nutrition, is always more liable than another to be the seat of local manifestation of blood-disease: it is, as they say, a *weak part*. Thus the old gouty or rheumatic joint is apt to receive the brunt of the new attack. And the same may happen in a more general way. A man was under my care with chronic inflammation of the synovial membrane of his knee, and general swelling about it: he was attacked with measles, and the eruption over the diseased knee was a diffused bright scarlet rash. A patient under Dr. Budd's care had small-pox soon after a fall on the nates: the pustules were thinly scattered everywhere, except in the seat of former injury, and on this they were crowded as thickly as possible. Thus, too, when a part has been injured, and it may be, is healing, a disease having begun in the blood will manifest itself in this part. Impetigo appears about blows and scratches in unhealthy children; erysipelas about the same in men with unhealthy blood. Such facts as

these appear to be sufficient evidences that morbid conditions of the blood are most probably the causes of the great majority of so-called spontaneous local inflammations; of such as cannot be traced to the direct influence of any external force, but appear, rather, as having an internal origin.

It may be added, that the state of the blood may determine not only the locality, but also the degree, and the form, and probable termination of the inflammation. But on this I need not dwell, having devoted a large portion of a former lecture to demonstrate that the products of even the same form of inflammation excited in the same tissue, may be different in different persons, according to the several peculiarities of their blood.

3. Respecting the disturbance of the third condition of healthy nutrition, namely, the due influence of the nervous force, as a constituent of the phenomena of inflammation, I have already spoken in a former lecture.* I now resume the subject, in the hope of showing that the disturbance of this condition may be one of the causes of inflammation.

To test the influence of the nervous force in engendering the inflammatory process, we must not, as is commonly done, take cases of the effects of external injury. Such an injury, or the presence of a foreign body, is supposed to excite inflammation by stimulating the nerves of the part, and by changing, through their influence, the state or action of the blood-vessels. This may be true; but we should remember that when a common injury is inflicted, it acts not only on the nerves of the part, but also on its proper tissues; and it may so affect the state of these tissues, that the changes produced in them may be the excitant of inflammation, independent of the affection of the nerves. All such cases as these are, thus, ambiguous. For a better test, we must select cases in which the excitant of inflammation acts (at least in the first instance) on the nervous system alone. Such cases are those already referred to. When the conjunctiva is inflamed after overworking of the eye, we cannot suppose that the light, by its direct contact, has affected the vessels, or the nutritive act, in the conjunctiva: it can, probably, affect either of these only through an influence reflected from the retina. So, when irritation of the urethra excites inflammation in the testicle; when the irritation of teething excites it in any distant part; when, as in a case quoted from Lallemand, by Dr. Williams, inflammation of the brain followed the application of a ligature to part of the brachial plexus;

* Lecture I. p. 12.

in these and the like cases—such as I mentioned in the first lecture,—we cannot but refer to the disturbance of the nervous force as the initiator of the phenomena of inflammation.

Now, for the explanation of such cases as these, there appear to be two chief theories—1. It may be that the nerves distributed to the minute blood-vessels of a part may be so affected that these vessels may dilate, and their dilatation may produce the other phenomena of inflammation; or, 2. The disturbance of the nervous force may more directly interfere with the process of nutrition, inasmuch as this force exercises always some influence in the nutrition of each part, and is (as one may say) one among the plasturgic forces.

The first of these theories has lately acquired a dominant place in systems of pathology, especially in those of Germany. The principal form of it, which has been maintained most prominently, by Henle, has enlisted the approval of even Rokitsansky, and is largely received, professing to explain all inflammations, and passing by the name of “neuro-pathological,” to distinguish it from the “humoral” and all other theories of inflammation. This theory may be thus briefly stated. The exciting cause of inflammation, whether an external cause, such as an injury of a part, or an internal one, such as diseased blood, acts, in the first instance, on the sensitive centripetal or afferent nerves of the part. These it affects as a stimulant, producing in them an excited state, which state, being conveyed to some nervous centre, is thence reflected on the centrifugal or motor nerves of the blood-vessels of the same, or some other related, part. This reflection, however, is supposed to bring about a kind of antagonistic sympathy, such that, instead of exciting the motor forces of the blood-vessels to make them contract, it paralyses them, and is followed by their dilatation or relaxation. This dilatation being established, the exudation, and other phenomena of inflammation, are assumed to follow as natural, and most of them as mechanical, consequences.

The eminence of those who have supported this hypothesis makes one hesitate in rejecting it; and yet I cannot help believing it to be groundless. If we remember that parts may present some of the phenomena of inflammation, though they have no nerves, as the firmest tendons and articular cartilages; that the degrees of inflammation in parts bear no proportion to the amounts of pain in them when inflamed; that the severest pains may endure for very long periods with only trivial, if any, phenomena of inflammation; that the

phenomena of the so-called reflex paralysis are rare, equivocal, and altogether insufficient for the foundation of a law or general principle; we may well think that there can be no sufficient ground for the invention of such an hypothesis as this. And, if we add that, even admitting the dilatation of bloodvessels as a possible consequence of the stimulus of sensitive nerves, yet the phenomena of even simple inflammation would be no necessary consequences thereof; that the varieties of inflammations would be quite unintelligible as results of similar mechanical disturbances of the circulation; and that the dilatation of bloodvessels, in any mechanical way produced, is followed by only feeble imitations of a part of the inflammatory process; then we may think that the hypothesis, if all its postulates be granted, will yet be insufficient for the explanation of the facts.

I believe that, if we would have any clear thoughts respecting the influence of the nerves in initiating inflammations, we must first receive the theory, referred to in the first lecture, that a certain exercise of the nervous force is habitually and directly engaged in the act of normal nutrition. If we admit this, there can be little difficulty in believing that the perturbations of the nervous force may engender the inflammatory mode of nutrition; especially when we see the normal and inflammatory modes connected through such intermediate instances as the increase of secretions when the nerves of a distant part are stimulated.

Now, that the nervous force has some other influence in normal nutrition than can be explained by referring to it only the government of the size of bloodvessels, we have, I think, ample evidence; and I cannot but wonder at the steadfastness with which some maintain or imply that the nervous force can manifest itself in nothing but impressions on the mind, and muscular contraction-force. So limited a view of the convertibility of nervous force, is such an one as the older electricians would have held, had they maintained that the only possible manifestations of electricity were the attractions and repulsions of light bodies, or that the electric force could never be made to appear in the form of magnetism, of chemical action, or of heat. We are too much shackled with these narrow dogmas of negation. The evidence of the correlation and mutual convertibility of the physical forces might lead us to anticipate a like variety of modes of manifestation for the nervous and other forces exercised in the living body.* We might

* For the suggestion I thank my esteemed friend whom I am glad to know correlated of the vital illustrated.

anticipate, too, that, as the nervous force has its origin in the acts of nutrition by which the nerve-substance is formed, so, by reciprocal action, its exercise might affect the nutritive acts. As (for illustration sake) the completed blood affects all the processes by which itself was formed, so, we might suppose, would the nervous force be able to affect all the acts of which itself is the highest product.

But we need not be content with these suppositions of the direct influence of the nervous force on the nutritive act, while we remember such facts as these. The mind can affect all nutrition, but it can do so only by affecting, in the first instance, the nervous force; and its effects are such changes of nutrition as cannot be referred to mere changes of the size of the blood-vessels. Abstraction of the nervous influence from a part by division, or other profound injury, of its nerves, is, as a general rule, followed by serious impairment of its nutrition, and by such and so various impairments as cannot be accounted for by paralysis of the bloodvessels. The direct influence of the nervous system on both the quantity and the quality of secretions is a fact even commonly noticeable; and secretion and nutrition are so similar processes that we may be sure they are accomplished by the same forces similarly exercised.*

We seem, then, to have sufficient evidence that the nervous force is one of those which (at least in the highest animals) are engaged in the normal act of nutrition; and sufficient evidence that inflammation may ensue in consequence of disturbance of the nervous force, even when that force cannot have acted in the first instance on the bloodvessels of the inflamed part. I think, therefore, the expression is justified, that the inflammation of a part may have its origin in disturbance of the nervous force which is normally exercised in the nutrition of the part, and which is exercised directly, not merely through the government of the contractile coats of the blood-vessels.

The last of the necessary conditions of normal nutrition in a part is the healthy condition of the part itself. If a part be at present diseased, it will be apt to remain so, because of the continuance of the same diseased method of nutrition. Now, it appears highly probable that a disturbance of the healthy state of a part may introduce the phenomena of inflammation. This is probable for many reasons; as, first, from analogy with normal nutri-

tion. Generally, the principal conditions of nutrition are the relative and mutual influences of the elements of the tissues and the blood. More particularly, the condition of the tissues determines, at least in great measure, both the quantity and the rate of movement of the blood supplied to them, the changes of the tissues, whether in growth or decrease, just preceding the adapted changes in the supply of blood. So we may believe a change in a part anyhow engendered may, by altering its relation to the blood, alter its mode of nutrition; and some of the changes may produce the inflammatory mode of nutrition, together with the altered supply of blood, and other characteristic signs.

Secondly, we may judge the same from the analogy between inflammation and the process of repair. Certainly it is the state of the injured part—i. e. of its proper tissues, not of its nerves and blood-vessels—which determines the process of repair: and some of the processes of repair are so like those of inflammation, that they are commonly identified, and are, perhaps, not capable of even a refined distinction.

And thirdly, the influence of the condition of the proper tissues of a part in initiating inflammation in it, is illustrated by more direct facts; such as, that injuries of parts that have no vessels or nerves are followed by altered modes of nutrition in them, these modes being more or less exact resemblances of inflammation. Thus, e. g. it is in the cornea, lens, vitreous humour, and the like, after injury.

On the whole, I think we may conclude that inflammation may have its origin in disturbance of the normal condition of the proper tissues of a part,—in such a disturbance as may be produced by injury, or by the proximity of disease. To this source, indeed, I should be disposed to refer nearly all inflammations that originate in the direct application of local stimuli, whether mechanical or chemical. It is true, that, in most cases, the stimulus affects at once the proper elements of the part, its nerves, and its bloodvessels, so that we cannot say how much of the disease is to be ascribed to the affection of each; but the fact that a process resembling, so far as it goes, that of inflammation may ensue after injury in parts that have neither vessels nor nerves, may make one believe that, in parts that have both, the inflammation depends mainly on injury, or other affection, of the proper tissue.

I have thus endeavoured to show that inflammation may take its rise, may have its proximate cause, in a disturbance of

* The subject is more fully illustrated in the Lectures on Nutrition, in the *MEDICAL GAZETTE* for 1847.

any one of the conditions of nutrition. In the examination of different cases, we find that, even while any three of the four chief conditions may be normal, yet a qualitative error of the fourth may bring in the phenomena of the inflammatory process and method of nutrition. In the necessity of choosing pointed cases, I may seem to have implied that it is usual for inflammation not only to begin, but to be maintained, by an error in one of the conditions of nutrition: but this is improbable. Rather we may believe, that many of the existents of inflammation may affect at once more than one of the conditions of nutrition; and, as I stated in the first lecture, it is nearly certain that in every inflammation, after a short continuance, all the conditions of the nutritive process are alike involved in error.

P.S.—I cannot but fear, lest, having seldom referred, in these Lectures, to the works of those who have written on Inflammation before me, I may seem unready to acknowledge my obligations to them, or desirous to receive unmerited praise for originality of observation or of thought. Nothing is further from my intention, or, I believe, from my custom. The truth is, when I began to prepare for the delivery of the lectures, it seemed impossible to study their subject-matter by both reading and personal investigation: its extent seemed almost equally boundless in books and in nature. I therefore determined to occupy my time almost exclusively with personal inquiries and reflections; and to add the results of these to whatever I found true in the knowledge previously acquired by reading or by earlier examinations. If I had had time to study the vast literature of inflammation, I would gladly have endeavoured to assign to its proper author whatever fact or opinion of any value these lectures may contain; but this was impossible: and now, though conscious of being largely indebted, I am quite unable to say to what creditor each debt is due. But I gratefully acknowledge that my greatest obligations were incurred, many years ago, in reading the works on Inflammation of Hunter, Lawrence, Tweedie, James, and Macartney; and that, more recently, I have borrowed both facts and suggestions from the writings of Mr. Travers, Dr. Carpenter, Dr. C. J. B. Williams, and my valued friend and former pupil Mr. Humphry. Nor are my obligations less to Rokitsansky, Henle, Virchow, Reinhardt, and, it may be, to many others from whom I may have derived such knowledge that I ought never to have forgotten whence it came.

CASE OF MOLLUSCUM FUNGÖIDES, OR TUBERCULOSA STYPHILOIDEA. BY M. LUCIEN CORVISART.

THE patient, a female, thirty-one years of age, was admitted into the hospital, Beaujon, under the care of M. Huguier. Her general health had always been good, and she was the mother of three healthy infants. She had resided two years in Paris, in the most unfavourable hygienic circumstances—in a damp room, in the midst of rags and old clothes, in which she carried on a brokerage. In the month of April, 1848, there appeared on the left side of her neck a prominent bluish-red tumor, of firm consistence. When first noticed it was as large as a pea, and in the course of six weeks acquired the size of a bean. Three months afterwards, this tumor was destroyed with Vienna paste. Fifteen days afterwards, eight other tumors appeared on the abdomen, which, however, disappeared in a short time without treatment. Towards the end of September she was seized with paralysis of the right side of the face. In December, ulceration of another tumor on the loins occurred. Fresh tumors also shewed themselves on the legs, thighs, abdomen, chest, and arms. At the same time, numbness and partial paralysis of the right forearm supervened; and lastly, in the beginning of January 1849, a tumor appeared on the middle of the forehead.

When admitted into the hospital, this patient had upwards of a hundred tumors, varying in size from that of a pea to that of a large nut, and in colour from that of a rose tint to deep red, adhering by broad bases, and presenting on their summits a slight elevation of cuticle from beneath, which exuded a scanty yellowish plastic serosity. Some of these tumors were ulcerated, presenting a pale excavation, with depressed or elevated base, granular and firm, the edges generally everted: some were covered by a layer of plastic reddish lymph. Besides these, large whitish-opaque *bullæ* were seen on various parts of the body, as the ends of the fingers, on the inside of the thumb and index finger, and on the back of the wrist. These *bullæ* were surrounded with indurated inflamed bases, and contained pus.

The disease did not yield to remedies, and shortly the patient died.

The autopsy showed that the tumors were composed of fibro-plastic tissue, with great vascularity of the superficial laminae of the skin. Beneath the frontal tumor, the periosteum was thickened, and in one place removed, leaving the bone exposed. Ulcerations of the palate were found. Two fibrous tumors were found in the substance of the right ventricle of the heart, also several in the uterus and ovaries. The liver was fatty to a great degree. The os uteri rated.—*L'Union Médicale.*

Original Communications.

ON THE
INDUCTION OF PREMATURE
LABOUR;

WITH CASES.

BY GEORGE HARVEY, SURGEON,
Castle Heddingham, Essex.

ANY interference with the natural process of uterine gestation, more particularly any attempt to produce premature labour, must be considered unjustifiable, except under very peculiar circumstances, endangering the life both of the mother and child,—such as profuse uterine hæmorrhage occurring in the latter months of pregnancy, or the previous knowledge of such deformity of the bones of the pelvis that a fœtus at the full period could not possibly pass entire. Under these circumstances an attempt to produce premature labour may be not only justifiable but advantageous, as I hope the following cases will clearly prove: but it must be confessed that, after having used all available means, we cannot possibly predict the time at which labour will commence.

CASE I.—On Saturday, April 11th, 1846, at about 8 o'clock p.m., I was summoned to Mrs. H—, who was that evening suddenly attacked with hæmorrhage from the uterus to a large amount (probably two pints). Has met with no accident; was previously in good health, and knows no cause for this occurrence. Considers herself wanting full six weeks of her time. Suffers very little pain. Bowels costive; pulse weak and fluttering.—*R. Magnes. Sulph. ʒij.; Infus. Rosæ (c. duplici portione Acidi), ʒvj.; sumat cochl. maj. ij. 4tis q. h. To be kept cool, and in a recumbent posture.*

12th, 10 o'clock p.m.—Hæmorrhage ceased; no pain; bowels relieved twice during the night: says she can feel the movements of the child.—*Rep. Mist. sine Magnes. Sulph.*

April 13th.—No hæmorrhage; more cheerful: says she can feel the child. I thought I could hear the child's heart by the stethoscope just above the crista ili, on the right side, but am not certain.

15th.—Again summoned at 6 o'clock this morning. Hæmorrhage returned to an alarming amount. No pain; very faint: says she can feel the child. On examination per vaginam, I found the os uteri very high up, and undilated, the cervix about half an inch in length. However, I succeeded in inserting the tip of my forefinger just within the entrance of the os uteri; then passing a flexible female catheter, with a perforation at its extremity, along my finger, it readily entered the cavity of the uterus. I now passed through the catheter a stilette with a sharp point, 1-8th of an inch longer than the catheter, and punctured the membranes: a large quantity of liquor amnii flowed readily through the instrument, and the hæmorrhage almost immediately ceased. I then gave her a scruple of ergot of rye, which I repeated at 8 o'clock, no perceptible effect having been produced. 10 o'clock.—Very comfortable: no hæmorrhage. Liquor amnii discharged at intervals. Slight pain in the abdomen and loins. Os uteri in the same state: ordered to remain in bed and be kept quiet.—*R. Pulv. Secale, ʒj.; Spt. Ether. Nitrici, ʒij.; Sacch. albi, ʒj.; Aquæ, ʒvj. Mix. Sumat cochl. maj. ij. 4ta q. hora.* 2 o'clock p.m.—Slight pains in the loins and abdomen: no hæmorrhage. I can perceive with the stethoscope a confused murmur on the right side near the crista ili, and an obscure pulsation synchronous with the pulse at the wrist, probably the iliac artery; but nothing of the kind perceptible on the left side. 10 o'clock p.m.—Slight pains still continue at intervals, but no hæmorrhage. Os uteri in the same state. Complains much of faintness, and wishes for a little beer, which I have permitted.

16th.—Very comfortable; rested well last night; took half a pint of beer, and some bread and cheese, with great relish. Very desirous of getting up, which I have forbidden. Os uteri remains the same. Still slight pains, accompanied with a discharge of liquor amnii. The hæmorrhage having ceased, I have discontinued the ergot, lest the constant contraction of the uterus should destroy the child, which the mother is still confident of feeling: to have broth and gruel, a little beer, but no medicine.

17th, 10 o'clock a.m.—Pains increased in strength: no hæmorrhage. Os uteri soft and slightly dilated. Presentation apparently the head. No attachment

of the placenta discoverable: but I did not interfere much, lest I should do mischief. 2 o'clock p.m.—Labour proceeding slowly: os uteri moderately dilated; presentation natural. Let well alone. 7 o'clock p.m.—A messenger to say that the pains were very severe. Found the os uteri fully dilated, but no attachment of the placenta to be detected. At 8h. 30m. a male child was born, which immediately cried lustily. After a few minutes, the pain returning, I grasped the uterus through the abdominal parietes, and the placenta was speedily expelled, without any traction by the cord, and without any hæmorrhage beyond what is usual.

On carefully examining the placenta, I found the cord inserted about an inch from its edge. At this part, and on either side, the chorion was separated from the edge of the placenta nearly half its circumference, and in width about half an inch. In this part there were numerous coagula; but I could discern no evidence of the spongy portion having been separated from the uterus previous to the birth of the child. I was unable to obtain possession of the placenta, which I was desirous of preserving. Did the hæmorrhage proceed from that part of the placenta from which the chorion was separated?

18th, 10 o'clock a.m.—Mother and child quite comfortable. Ordered the child to be put to the breast. The recovery of the mother was speedy and complete.

CASE II.—On the 20th of June, 1847, the mother of L. C. called to inform me that her daughter, whom I had delivered with the crotchet rather more than a twelvemonth since, was again pregnant, and requested my attendance. She could not say when it might be expected, having never menstruated since her last delivery, but thought she must be more than half her time. I now informed both her mother and herself that the difficulty experienced in her last labour arose partly from the large size of the child, but principally from the unfortunate deformity of her own person (a very short woman, with the promontory of the sacrum projecting to little more than two inches of the pubis). I therefore advised her to allow me to induce premature labour two months before the full period: to this she made not the slightest objection.

I then desired her to endeavour to recollect the time at which she had quickened, informing her that twenty weeks from that time would amount to the full period, and that I wished to bring on labour eight weeks before the regular time.

August 7th.—Being in attendance on a neighbour, I called on her, when she informed me that she was very uncomfortable, on account of the great size and weight of her body, and that she considered she had barely two months before her full period would be completed. This was about noon. I promised to see her in the evening, and desired she would summon her mother, and have everything prepared, as I should endeavour to bring on labour, with the hope of saving the child, and without risk to herself. 5 o'clock p.m.—Found no difficulty in reaching the os uteri with the forefinger of my left hand, on which I introduced a flexible female catheter, perforated at its extremity, and passed it fairly through the os uteri till it met with some resistance. I then passed a stilette, and the liquor amnii flowed freely through the catheter. I desired her to remain in bed, and to send to me when labour pains commenced. 11 o'clock p.m.—Her mother called to inform me that she had felt a few very slight pains, and that the waters were constantly dribbling away. Desired to be called if the pains increased either in strength or frequency.

8th, 12h. 30m. noon.—Pains rather more frequent, but very slight.—Secale Cornuti, \mathfrak{ss} . statim. 7 o'clock p.m.—Pains stronger; os uteri fairly dilated; head presenting, but advances very slowly. Half-past ten: delivery completed 29 hours and a half after puncturing the membranes. Child, a son—still-born; several patches of ecchymosis on different parts of its body, particularly one extending over the whole of the right shoulder, and another covering the entire scalp. This I consider to have been caused by the pressure of the uterus after the evacuation of the liquor amnii; and this pressure, although the pains were never violent, may have caused the death of the fœtus, which does not appear to have advanced beyond the sixth month; therefore the woman must have made an erroneous calculation. I would not, except in cases of hæmorrhage, or some other extraordinary emergency, advise premature

delivery earlier than the thirty-second week of utero-gestation, which was the time represented to me in the present instance.

CASE III. — December 24th, 1849. L. C. this morning called to inform me that she was again pregnant, and in her twenty-seventh week: that she was confident of the correctness of her calculation, and begged that I would again deliver her before the full time. I enjoined her to pay strict attention to the state of her bowels, and to let me know if at any time she had pain or uneasiness, and desired her to have everything prepared, as I intended to be with her eight weeks before the full period.

Thursday, January 24, 1850. — I visited her this morning, informed her that I intended to be with her on the following Monday, January 28, gave her some aperient medicine, and engaged her husband's mother to be in attendance.

28th. — On examining per vaginam I could just reach the os uteri, but not sufficiently to introduce a catheter with certainty; therefore gave her *Secale Cornuti*, ℞j. at 12 o'clock. 5 o'clock P.M. — Has had slight pain in the abdomen, and vomited twice. I can now reach the os uteri with ease, and therefore introduced the catheter and punctured the membranes, as in her former labour. Desired her to remain in bed, and send for me if the pains increased.

29th, 9 o'clock A.M. — But little increase of pain. Liquor amnii has been freely discharged. Os uteri soft, but very slightly dilated. 5 o'clock P.M. — Much the same. Resolved not to repeat the ergot; as in her former labour I suspected it had, by exciting the uterine action, caused the bruises and consequent death of the child: the dose given yesterday, with the view of dilating the os uteri and bringing it within reach, could have no such effect, as the membranes were not then ruptured.

30th, 11 o'clock A.M. — Pains increasing in strength and frequency; but I cannot discover any presenting part. She assures me that the child is living, but I cannot ascertain it by the stethoscope. Bowels relieved this morning. 4 o'clock P.M. — Os uteri more dilated. I can just feel what I believe to be the head resting on the brim of the pelvis. 11 o'clock P.M. — Pains rapidly increasing, and very severe. I can now clearly

distinguish the head just entering the pelvis. 12 o'clock. — Head gradually advancing. At 10 minutes before 1 o'clock in the morning, during a very severe pain, the child was expelled, about 56 hours after puncturing the membranes. The head was much flattened and elongated, but the child breathed, and cried feebly: wrapped it in a warm flannel, and placed it in a woman's lap before the fire, the night being intensely cold. In about half an hour, having given it a teaspoonful of weak gin and water, it began to cry strongly, and to breathe with freedom. After having given the usual directions for the care of the mother, to whom I gave thirty drops of *Tinct. Opii*, I directed the child to be washed and wrapped in a warm flannel, and, on account of the extreme cold, to be placed in a warm bed with the woman who first received it, but not with the mother, lest she should be disturbed by its presence, and not to be dressed before my visit in the morning.

31st, 10h. 30m. A.M. — The mother has passed a tolerable night, and is comfortable this morning. The child breathed freely, and cried loudly till about 9 o'clock this morning, when the mother, awaking from a sound sleep, found it dead by her side, whither it had been conveyed contrary to my positive orders.

February 1st. — Very comfortable.

3rd. — As well as women usually are. Bowels relieved naturally this morning.

CASE IV. — Mrs. Elizabeth C —, Feb. 22nd, 1850, sent this evening in great haste to inform me she was in labour. On my arrival I found that, according to her own reckoning, she wanted full ten weeks of her full time, but was alarmed by a sudden attack of hæmorrhage unattended with pain. The hæmorrhage was slight, but, as she was greatly alarmed, I remained with her about two hours. No pains coming on, I desired her to remain in the recumbent position, to be kept cool, and have no stimulants. I then gave her twenty drops of *Tinct. Opii*, and left her.

23rd. — Slept well during the night. No pain. Hæmorrhage continues, in a fluid state. No coagula; no heat or tenderness of the abdomen. Says she feels the child very clearly. Pulse firm, and not too frequent. On examination per vaginam, with the intent of rupturing the membranes, I found that I could

not reach the os uteri: I therefore gave a scruple of ergot, hoping to excite the action of the uterus, and, as soon as I could get my finger introduced, intended to perforate the membranes with the catheter. The ergot produced sickness and a little pain in the abdomen. After about an hour, on examination, I could just reach the os uteri, but not sufficient to introduce my finger. The hæmorrhage has nearly ceased; and, as I suspect the placenta is situated near or over the os uteri, it will be hazardous to try the catheter, which might pierce the placenta and increase the hæmorrhage.—*R. Secale Cornuti, ʒi.; Aquæ, ʒviij. Coque ad ʒvj. et cola. Sumat cochl. maj. ij. 4 v. 5. q. h.*

24th.—Much the same. Mixture caused sickness, but no pain. To remain in bed, take nourishing food, but no stimulants.

25th.—Hæmorrhage nearly ceased. Is very desirous of getting up, which I have strictly forbidden.

26th.—Contrary to my orders, she came down stairs this morning, but, becoming very sick and faint, she was obliged to return to bed. No increase of hæmorrhage, but complains of constant nausea. Bowels relieved this morning.—*R. Sodæ Carbon. ʒij.; Tinct. Cardam. comp., ʒij.; Infus. Gent. comp., Aq. Ment. Pip. aa. ʒijj. Mix. Sumat cochl. ij. ter in die.*

27th.—Considers herself better to-day. Very little hæmorrhage; no pain; appetite good. The neighbouring gentry are exceedingly kind in sending supplies of food; but I have strictly forbidden wine, spirits, or beer.—*Rep. Mistura ut heri.*

March 1st.—The membranes ruptured spontaneously last night about 12 o'clock, when I was immediately summoned. Found a very copious discharge of liquor amnii, and some increase of hæmorrhage, but no coagula, and very slight pain. On examination, the os uteri was easily felt; but I could only just introduce the extremity of my finger. The cervix uteri is about an inch in length, and very flabby.—*Capt. Pulv. Secalis Cornuti, ʒj. statim.* After remaining with her about an hour, finding no increase of pain or any indication of labour, I left her, desiring to be sent for if pain or hæmorrhage occurred.

2nd.—Liquor amnii, deeply tinged with blood, continues to dribble away,

but without pain. Vomited after I left her yesterday, and still complains of nausea and faintness: pulse 84, and of good strength; bowels regular.—*Rep. Mist. c. Infus. Gent., as prescribed Feb. 26th.*

5th.—Much the same; no indications of labour; os uteri in the same state. Complains of being so long confined to bed; but I explained to her friends and herself the danger of allowing her to get up. Says her medicine comforts her.—*Rep. Mist.*

10th.—Received a message from Mrs. G—, a lady residing in the neighbourhood, requesting that I would summon any assistance if I considered it necessary, offering to pay the expense, even if I thought proper to summon either of the London practitioners in midwifery.

11th.—No alteration. I now determined to avail myself of the very liberal offer of Mrs. G—, considering that if anything unfavourable should occur I should be deservedly censured for not calling further assistance. I therefore called on my friend Mr. Carwardine, of Earl's Colne, and gave him a full statement of the case; on hearing which, he replied that he had been so many years unaccustomed to midwifery practice, that he did not feel sufficient confidence to act in the present case, but considered that my treatment hitherto had been very judicious, and that at present I was not warranted in further interference. However, he recommended me to state the case to his neighbour Mr. Taylor, of Earl's Colne, a general practitioner, about my own standing in the profession. We immediately went together to Mr. Taylor's house, and, on stating the case, Mr. Taylor agreed with Mr. Carwardine and myself, that until more urgent symptoms presented themselves the case had better be left to nature. However, he accompanied me to the patient's house, and after a patient examination per vaginam, and repeated questions relative to her former and present feelings, decided that further interference was not required. We therefore desired her to keep perfectly quiet, and endeavoured to comfort her by assuring her that we all considered it best not to interfere; that although true labour pains might be daily or hourly expected, it was possible that she might complete the full period.

April 1st.—A hasty messenger about

6 o'clock this evening, informing me of a sudden gush of blood to a very considerable amount had just taken place. On my arrival the hæmorrhage had nearly ceased: no pain. On examination the os uteri presented the same closed condition as before: I therefore enjoined perfect quiet, the application of cold vinegar and water to the pubes, and left her.

2nd.—Hæmorrhage nearly ceased.

4th, 7 o'clock p.m.—A sudden accession of pain, but without hæmorrhage. On examination I found the os uteri well dilated, and flaccid. Breech of the child presenting: pains strong, and at short intervals. I had fully expected a presentation of the placenta, but on the most careful examination can discover nothing of the kind. At 45 minutes after 8 o'clock, full five weeks after the rupture of the membranes, the child, a female, was expelled, apparently wanting 7 or 8 weeks of the full period: after gasping with attempts at respiration for about three minutes, it expired. The placenta, which was situated at the back part of the uterus, near the fundus, was thrown off about ten minutes after the birth of the child; but no appearance as though any part of it had been torn or prematurely detached could be detected.—*Sumat Tinct. Opii, gtt. xxx.*

5th.—Very comfortable, and as well as women usually are, and very thankful for my attention. Her complete recovery was not interrupted by any untoward circumstance.

Castle Hedingham, May 20th, 1850.

TREATMENT OF BURNS. BY DR. REESE.

AMONG the most numerous cases brought into the surgical wards of charity hospitals everywhere, may be reckoned the injuries received by burns and scalds, which, when extensive, are too often fatal. In the treatment of these injuries, we have had great experience and uniform success, when the patients were brought in soon after the injury. No fatal case of recent burn or scald has occurred in the hospital, although several have been extensive and severe. The universal treatment of all such cases is to cover the parts with wheaten flour thrown over the wounds by a dredging-box, which, if thoroughly done so as to exclude the air, and prevent its temperature from reaching the suffering tissues, will afford instant relief from pain, and allay all that nervous irritation which is

the chief source of immediate danger in all cases of extensive burns. We have had opportunity to test this practice in terrible burns occasioned by explosions of gunpowder, in scalds from the bursting of steam-boilers, in examples of persons while drunk falling into the fire, and others in which the clothes were burnt off the body by the combustion of spirit gas, &c. In all these cases,—and in some of them scarcely any portion of the body had escaped,—and notwithstanding, in a few of them, the integuments were literally baked, so that extensive and deep-seated suppuration and sloughing were inevitable, and had afterwards to be endured,—the external application of the flour was in the first instance our only remedy, and this was continued for one or more days while the acute effects of the injury demanded it. The superficial portions of the burn or scald would often heal under this application alone; and the solutions of continuity, more or less deep, which remained open and discharging, were then dressed with lime-water and oil, by means of a feather, to which creasote was added if the granulations were slow, or the sloughs tardy in becoming loose. Under this dressing the most formidable burns have been healed; and, even when the face has been involved, there has been scarcely any considerable deformity. In one of our patients, the face being horribly burned by an accidental explosion of gunpowder, the grains of powder having been embedded in the skin, very great apprehensions were indulged that the discolouration thus produced would permanently disfigure and deform the countenance. But, after the persistent application of the flour for three successive days, and until the tumefaction of the face and head had subsided, it was found that, with a few applications of the lime-water dressing, the cicatrization was complete, and even the discolouration was removed.

If this simple remedy were resorted to in the severe scalds sometimes occurring from explosions of steam-boat boilers, &c., there can be little doubt that the fatality of such burns would be very rare; while the popular and mischievous methods of applying raw cotton, oil, molasses, salt, alcohol, spirits of turpentine, sugar of lead water, ice, &c., to *extensive and deep burns*, are all of them injurious, and often destructive to life.—*American Journal of Med. Sciences*, 1850.

. When the burn is superficial, one of the best applications is to cover the skin with a varnish of dextrine applied in successive layers. *Probatum est.*

A CASE OF
DISEASE OF THE SPINAL CORD,
IN WHICH THE SYMPTOMS
SUPERVENED UPON A RECENT COLD:
SMALL-POX HAD PRECEDED ONE YEAR,
AND INJURY TO THE SPINE
TWELVE YEARS.

BY J. F. MARSON,
Surgeon to the Small-Pox and Vaccination
Hospital, London.

(*Read at the Westminster Medical Society,
May 11, 1850.*)

THE subject I am desirous of bringing under your notice this evening, is a case of disease of the spinal cord, the particulars of which I will endeavour to relate to you as accurately as I can, just as they appeared during the progress of the patient's illness, and after death on dissection.

Joseph Thomas, a black, a native of Nova Scotia, 22 years of age, was attacked, in the beginning of March 1845, with symptoms such as are produced by a common cold. He had been employed as a servant in the wards of the Small-Pox Hospital for about twelve months, subsequently to being a patient there with small-pox, which disease he had in a mild form. He was an active, intelligent man, of middle size, and rather slight form. During the first few days of his illness he was allowed to sit up and amuse himself, without doing any work; but the symptoms of his disease increasing, he was, with some reluctance, prevailed on to confine himself to bed: his pulse at that time was soft, and from 90 to 100 in the minute. He had thirst, a furred tongue, and copious perspirations. At the end of a week he complained of stiffness of his neck, and pain on attempting to move his head from side to side; and he stated that he had had flying pains in his neck and shoulders at night, occasionally, for a month or six weeks past. After being confined to his bed for about a fortnight, he began gradually to lose the use of his arms, and subsequently of his lower extremities. This was followed by retention of urine, and his stools were passed involuntarily. His bladder was emptied night and morning with the catheter for ten days, when he passed

his water also unconsciously; and from this time there was a constant dribbling of urine, the bladder remaining in a contracted state. He had complete loss of voluntary motion in all parts supplied with nerves below the fourth pair of cervical nerves. Sensation, however, did not appear to be in any respect altered, either by increase or diminution. Increased sensibility is considered by Ollivier* a sign that the membranes of the cord are inflamed;—diminished sensibility, a sign of inflammation of the cord itself. The patient's respiration was easy and free, his deglutition good, and he was without pain in any part of his body, except in his neck, and only there on motion. His appetite was good, and he slept well. He had no pain on percussion over the spinous processes of the vertebrae, no rigors, and no headache. His intellect was in no way affected all through his illness, nor was there any indication of his brain being implicated. Amongst the most common and the most striking symptoms described by Ollivier and Abercrombie, in their works on diseases of the spinal cord and membranes, are muscular rigidity, twitchings, or convulsions: yet there were no such signs to guide us in the case now under our consideration;—no movements could be excited in either the upper or lower extremities by tickling the soles of the feet or palms of the hands, or other parts of body, with a feather.

It was, however, tolerably evident, from the symptoms detailed above, that there was some mischief going on insidiously in the spine, most likely of an inflammatory nature; but from the softness of the patient's pulse, and the profuse perspiration, it was not judged to be proper to employ general bleeding; and there was no pain nor tenderness on percussion over the spinous processes, to indicate where local bleeding might be of service. Purgatives and saline medicines were administered; the patient was kept in bed, and on low diet. Bleeding not seeming to be admissible, he was very early brought under the influence of mercury, so as to make his gums slightly tender, which was continued for more than a fortnight; and a narrow blister was applied from the nape of the neck to the lumbar region. The greatest care was taken

* *Traité de la Moelle Epinière, et de ses Maladies*, 2me édit. t. ii. p. 598.

to keep his bed as dry as possible, by the use of the urinal, &c.; but from his constantly lying in one position, without the power of moving in any way, he soon had a sore formed over the sacrum. Directly that this sore was discovered, he was placed on an India-rubber collar or crescent; but a large slough formed, which appeared to be the proximate cause of death, after an illness of seven weeks. Not the least pain was ever felt in the wound over the sacrum, although sensation was good in all other parts of the body. I may perhaps be allowed to state here, that, owing to the great pain experienced in moving the head forward, I predicted, three weeks before the patient's death, that there was pus in front of the cervical portion of the spinal cord, but that in all likelihood the cord itself was not materially diseased in this part; because the muscles of the chest and abdomen were used in breathing, which would most likely not have been the case had the cord been seriously diseased in the upper part of the spine. This prognosis proved to be correct on dissection.

Post-mortem examination.—Lapse of time after death, twenty-four hours. The spine was carefully examined in its whole course. There was purulent deposit on the anterior surface of the theca vertebralis, occupying about 5-6ths of the whole of the cervical portion of the canal; but the cord itself in this part was not diseased. About six inches of the membrane of the dorsal portion of the cord was much congested, and its cellular tissue infiltrated with a gelatinous effusion, opposite to the lower dorsal vertebrae. The entire cord was somewhat softer than natural; portions of which, of variable extent, were completely disorganised, and reduced to a semi-fluid condition. The fluid found in the vertebral canal could not be said to be in unusual quantity. The medulla oblongata and pons varolii appeared to be quite healthy. Some years ago, when a boy about ten years old, this man received an injury from a horse, by being thrown down and trampled upon; but there was no breach of surface, the parts at the time appearing only to have been bruised: but now, two of the right transverse processes of the seventh and eighth dorsal vertebrae were discovered to have been fractured opposite to the softened and

congested part of the cord and membranes; and in the areolar tissue surrounding these transverse processes there was slight, but evident purulent infiltration. The processes were loose, and the separated or disunited ends in a state of ulceration: they did not appear ever to have united after the fracture: but of this it is impossible to speak with certainty. Ample evidence being found at once, on opening the spine, to account for all the symptoms of disease shown during the fatal illness, other parts of the body were not examined.

I looked upon this case at the time as one of those untoward occurrences and intricate forms of disease, that we meet with every now and then in practice, the approach of which it is perhaps impossible for us to foresee, or, if foreseen, to prevent. Considerable mischief has usually been done in such cases, and the disease has made great progress before the symptoms of it are such as to guide us to a decision as to what is probably going on. The patient in this instance had been at work just before his illness appeared, cleaning the balusters of a staircase, and being an industrious man he had worked hard, and perspired freely, on a cold windy day in the spring, with a window open at the top of the staircase, and another at the bottom. This I look upon as a most dangerous position for a person to be working in: I had remonstrated with him for doing so; and I have remonstrated with others since repeatedly for the same thing, but all to no purpose: they seem to enjoy the breeze, and disregard the caution given. It is, however, likely that the mischief thus done would have passed away as a common cold, but for the predisposition to disease arising from the injury received from the horse some years previously, influenced somewhat, probably, also by his late attack of small-pox. Injured parts are disposed to take on morbid action when brought under exciting causes. Of this we must all have seen examples. A striking instance came under my notice a few years ago:—A sailor, on jumping from his ship to the pier, lost his balance, and fell back on the ship, striking the calf of his leg against the side of the vessel. No harm came of the blow at the time; but several months afterwards he caught small-pox, and in the

progress of the disease a deep abscess formed in the calf of the leg, between the gastrocnemius and soleus muscles, which I had occasion to open, and had to cut completely through the gastrocnemius muscle of a strong muscular man before I reached the pus.

It may perhaps be thought by some, that this man with disease of the spinal cord ought to have been bled at the onset of his illness; and I am not prepared to say, if we could then have been quite sure what was going on, and what would be the result, that it might not have been serviceable: but I have stated that there were reasons against bleeding—namely, a soft pulse, profuse perspirations, and the constitution of the black. Blacks do not, in this country, so far as I have observed, bear bleeding so well as the Englishman does. Besides, I will state to you what our distinguished surgeon, Sir B. Brodie, says, in an excellent paper on disease of the spinal cord arising from injury, on the subject of bleeding.* He says to the effect, that in injuries of the spine, followed by inflammation of the membranes, it will be proper to take blood from the arm, and perhaps to repeat the bleeding; but it should be remembered, that in cases of injury to the spine the patients do not bear bleeding so well as after injuries of the head. "It is, however," he continues, "if my experience has not much misled me, a great mistake to suppose that blood-letting is always proper. In the majority of cases the state of the pulse is such as actually to contra-indicate the abstraction of blood; and the blood, when drawn, does not in general present those appearances which are supposed to mark the existence of inflammation. I have no reason to believe that blood-letting arrests the process of softening and dissolution of the spinal cord; and, indeed, I have usually found that the symptoms which mark the existence of these changes make a more rapid progress in proportion as a larger quantity of blood is taken away." Now if bleeding be considered improper in some cases of direct and perceptible injury to the spine, it may well be employed with hesitation in cases involved in great doubt, where there has been no known injury done. That there are exceptions to the use of bleeding I have no doubt, and I believed, and

still believe, this case one; at the same time, I think, as a general rule, it will be well to employ bleeding, general and topical, at the *very beginning* of the illness, if we can make up our minds that there is inflammation going on in the cord; but when the disease has existed for some time—say a fortnight or three weeks—it may then fairly be questioned, whether bleeding is a judicious measure to adopt or not.

And here I feel that our best powers of perception and diagnosis will be required to guide us to a correct decision. The part diseased is surrounded by a strong bony covering, so that pressure upon it does not produce pain. Mr. Copeland* has suggested an admirable means of assisting us in our diagnosis of these intricate cases: he says, when there is no pain on pressure over the spine, "he has frequently detected the seat of the disease by the part being more susceptible of the stimulus of heat: a sponge wrung out of hot water and carried down the spine, will often give a very acute degree of pain while passing over the part where disease is going on." This test, however, I need scarcely remark, will be of no use to us in those cases where sensation, as well as voluntary motion, has been lost.

When similar cases come under our care, we should watch them with the very greatest vigilance at the commencement, in order to make out if possible, and as early as possible, the exact seat of the inflammation; for inflammation I suppose it is, in nine cases out of ten, in its origin. I feel convinced, upon reflecting on these cases, that our only chance of doing much good will be at the beginning; our early remedies will be those of the greatest use, and they should be employed as boldly and decisively as circumstances will permit; bearing in mind that it is only in the early stage that the progress of the disease is much under our control. Let a fortnight or more go by, and then our depletory measures will most likely do more harm than good. It is, it appears to me, one of those cases in which the rule *principiis obsta* is most essential to observe and act on. When, however, the disease is in a chronic state, I can readily understand that repeated bleedings will only tend to weaken the body without relieving the disease, and only hasten the

* Med.-Chir. Trans. vol. xx. p. 162.

* Obs. on the Symptoms and Treatment of the Diseased Spine, p. 35, 1815.

termination; as stated by Sir B. Brodie. But then it is not our custom generally to use repeated bleedings, nor do we expect to cure other forms of chronic inflammation by bleedings: we resort to different means of relieving it, mercury and counter-irritation for instance; and the same rule of treatment will, I take it, apply here as in other forms of chronic inflammation: but this does not militate at all against bleeding in the early stage of the disease, when, as is not uncommon, there are active symptoms. At the same time, it should be remembered, there are forms of the disease of an asthenic character from the first, scrofulous, perhaps, assuming a low form of inflammation, but still inflammation, although not such as would justify us in employing bleeding. Whilst expressing my belief, earnestly as I have done, that bleeding and other active measures should be employed at the commencement of the disease, I would again say,—and especially with reference to bleeding,—but let them be resorted to only after the most mature deliberation. And I feel that I ought to quote a few words from the admirable work of Abercrombie, on disease of the spinal cord: he says,* “Several very remarkable cases have occurred to me which presented all the characters of disease of the spinal cord, while nothing could be found, either in the brain or the cord, that could in any degree account for the symptoms.” He then describes carefully four cases, having paralysis and other symptoms of disease of the spinal cord, in persons in whom no disease could be detected after death, either in the cord or brain: still they had died, and we may fairly presume not without a cause. These cases are followed by the relation of several others, with similar symptoms, which recovered.

Sir B. Brodie,† Andral,‡ and Rostan,§ are of opinion that softening of the brain and spinal cord may take place independently of inflammation. Abercrombie,|| Ollivier,¶ and Lallemand,**

on the contrary, believe that inflammation at some period has always been the cause of it: and I confess myself to have coincided with the latter opinion, until I read an account of the investigations on this subject, made with the microscope, by Dr. Hughes Bennett* of Edinburgh, who has shown that the most important changes may take place in the cerebral substance, inappreciable to the naked eye, but clearly discernible with the microscope. He states “that two kinds of cerebral and spinal softening exist—an inflammatory and a non-inflammatory—which may always be distinguished from each other by means of the microscope: that inflammatory softening is characterised by the presence of exudation-corpuscles and granules, whilst in non-inflammatory softening these bodies are never found: that the nature of inflammatory softening consists in the formation and development of nucleated cells in exuded blood plasma; whilst the nature of non-inflammatory softening consists in the mechanical destruction or maceration of the nervous tissue in serum, or is the result of putrefaction: that the inflammatory and non-inflammatory softenings have been confounded together by morbid anatomists, it being impossible to distinguish one from the other, with any certainty, by the naked eye.”

I have not brought this case before you simply for the purpose of detailing what may perhaps be termed an anomalous case of disease of the spinal cord and membranes, or at least so in some of the points belonging to its history; but for the purpose of connecting it with like diseases of these parts, in which the symptoms are much the same at the onset of the illness, so that we may discuss, and make up our minds, so far as may be proper to do so, what we would do in the way of treatment in similar instances. At the time when bleeding, and other active remedies, would probably be of the most service, the nature of the disease is often unfortunately veiled in great obscurity, and it is only after it has made considerable progress that its true character becomes distinguishable.

One other feature in the case remains for me to bring prominently before

you. There is the possibility of this disease of the spinal cord having been the result of, or in some way owing to, the attack of small-pox. Such an occurrence has not before come under my knowledge, and I confess that the probability of its being the cause of the disease of the spinal cord in this instance had not crossed my mind (as the man had been to all appearance entirely well from the small-pox for nearly twelve months), until I was asked lately whether I had ever known such an effect to follow this disease, as two cases, apparently to be ascribed to that cause, had lately taken place: there was not, however, any *post-mortem* examination of either of them. On looking over the able treatise of Ollivier,* on the Spinal Cord and its Diseases, I find that three cases are alluded to by him of disease of the cord, two occurring after petechial, and one after intermittent, fevers. He, however, did not see one of them: two of the cases are by Bréra, the third by Petronelli,† this case having been treated at the garrison of Barcelona. There is a fourth case related in the work of Racchetti,‡ of a girl ten years old, who had inflammation of the spinal cord and membranes, and puriform matter about the *canda equina*. Reflecting on the subject, it appears surprising that such cases are not presented to our notice more frequently, when we call to mind how often we meet with disease of the brain. All of my hearers are aware that great constitutional disturbance takes place on the approach of the exanthemata: in small-pox more especially, there is nearly invariably, in the early stage of the disease, great pain in the dorsal region of the back, apparently to be ascribed to congestion and swelling of the vessels of the spine, affecting particularly that part where there is least room for such enlargement, and where it consequently gives most pain, as first observed and stated by Mr. Earle,|| with reference to other forms of spinal disease.

|| Phil. Trans. p. 282, 1822.

The points, then, that appear to me to admit of discussion, in addition to those that will doubtless suggest themselves to your own minds, are—

1. Was this disease of recent date, arising from, and the result of, cold and inflammation? or,

2. Was it a disease that had been coming on gradually, as instanced by the shooting pains in the neck and shoulders occurring occasionally at night for five or six weeks before the final attack, connected in some way with the disturbance that takes place in the system on the approach of all the exanthemata, and as one of the consequences, in the case before us, of *variola*? or,

3. Was it a case of *ramollissement* of the cord that had been going on slowly for years, dating its origin from the time when the injury was received from the horse, and the transverse processes of the vertebræ were fractured, and probably other violence done at that time to the spinal column?

Whichever of these points may be decided on as having been the probable cause of the mischief,—and I would beg to say that we have a better opportunity of deciding on them, now that the case has terminated, and given us an opportunity of examining the body, than when it was under treatment,—will somewhat influence the opinion we may form on the propriety of the remedial measures that were or ought to have been employed. If, for instance, we view the case as an attack of meningitis of the cord, or of myelitis, or both, arising from cold, depletory and other remedies for the subdual of inflammation will be considered to have been proper: if, on the other hand, we view it as the result of small-pox, occurring twelve months after this disease; or, going back still further, as dating its origin from the time when the injury was received from the horse in early life, then, I fear, the resources of our art must be deemed to have been altogether unavailable for affording relief.

COMPOUND FRACTURE OF THE THIGH.

FOUR cases of recovery, without amputation, are recorded as having occurred in four years; one gunshot, the others from falls or other violence. All were in young men of good constitution. The duration of the case was, in no instance, less than a year.—Dr. Hartshorne, in *American Journal of Med. Sciences*, Jan. 1850.

MEDICAL GAZETTE.

FRIDAY, JULY 19, 1850.

THE latest Memorial* addressed by the Society of Apothecaries to the Home Minister, is a document worthy of the attentive consideration of the profession. It directs itself to two points—on the one hand, to a general defence of the conduct of the Society and the designation of its licentiates; and, on the other, to a proposed alteration of its powers, so as to meet the views and wishes of at least one section of medical reformers. It is chiefly to the latter point that we wish especially to direct the attention of our readers.

The first proposition is to alter the mode of electing *examiners*. Instead of restricting this office to members or shareholders in the City Company, it is proposed to admit licentiates of ten years' standing; and it is advised that not less than one-half of the Court should consist of licentiates who are *not* members of the Society.

This is undoubtedly a liberal proposition: the only question which is likely to arise respecting it, is whether the best men to be selected as examiners in the different departments of medical science will always be found among the licentiates of the Society? Will the men best qualified to examine in Medicine, Chemistry, Midwifery, and Materia Medica, possess the Apothecaries' licence? The fact of their practising as licentiates must deprive them of those opportunities of special study which are necessary to qualify a man for properly conducting an examination in some of these subjects. We do not exactly see why an examiner should necessarily be a licentiate; or why a man otherwise well qualified, but not a

licentiate, should not be permitted to offer himself for election. Still we must admit that the Society are here only following the example of other institutions, if we except the College of Surgeons in its regulations recently issued. The examiners in Classics, Mathematics, Logic, and Languages, are fortunately not required to be members of the College!—Probably the Society believe that they will always be able to find among their licentiates, men possessed of quite as much knowledge of the medical sciences as may be sufficient to conduct an examination for the license. If this be the view upon which the restriction is based, we have nothing more to say to it. Time alone will show whether such a limitation is judicious.

In respect to *examinations*, the student will, we doubt not, be greatly benefited by the proposed change. An examination on so many branches of study conducted at *one* sitting, is not a fair or a just way of testing the knowledge of a candidate. His mind will necessarily become confused by the multiplicity of subjects to which it must be almost simultaneously directed; and a well-qualified person may be thus rejected, while a man of sufficient assurance, and with the aid of cramming, may readily get through the examination.

On the proposed alteration of the *fee* for the Certificate of Qualification, the Memorial is not very clear. The Society propose that it should be *equalized* for the whole kingdom; but they do not say whether it is to be equalized by lowering the fee to six, or raising it to ten guineas.

The alteration of the *place* where the examiners meet is a matter which concerns their own convenience. It probably implies the building of a new College for examinations, and the formation of a Museum, Library, &c.

* See p. 125.

The abolition of the *apprenticeship*, and the legal *registration* of all persons licensed to practise by the Society, are important improvements, which have been long urgently demanded.

The next clause, regarding the admission *without* further *examination*, and upon the payment of a small registration fee, of all persons holding a degree in *Medicine* granted by any British University, and of all members of Scotch or Irish Colleges, legally authorised to grant licenses for the practice of *Medicine* after examination, is highly liberal: it shows a *bonâ fide* desire to secure the public; and not that greediness for fees which has been sometimes charged against the Society. The same remark applies to Army and Navy Surgeons after five years' actual service. Those who will benefit by this clause will be the possessors of British diplomas to practise *Medicine*. A surgical diploma alone will not give this right to an *ad eundem* license at Apothecaries' Hall.

Some consideration is required in order that this liberality should not give rise to abuse. A student must not be led to seek for a University or College in Scotland or Ireland, where the examination may be comparatively easy, and then claim the English license of the Apothecaries' Society. This would defeat the purpose of the provision. The Apothecaries' Society should insist upon an *equality of examination*. This, however, is a matter of detail. The propositions of the Society would render a new College of General Practitioners unnecessary; and it remains to be seen whether they will be accepted by the Government.

ROYAL COLLEGE OF SURGEONS.

LECTURES ON THE TREATMENT OF DELIRIUM AND COMA;

(IN SEQUEL TO THE LUMLEIAN LECTURES
FOR 1850.)

Delivered at King's College Hospital,

By R. B. TODD, M.D., F.R.S.

(Reported by Mr. LIONEL S. BEALE, Med. Associate K.C.L.)

LECTURE V.

Treatment of the delirium of scarlet fever and other exanthemata—The delirium of typhus or typhoid fever—two forms—Nature of typhus fever—outline of its treatment—use of stimulants—local treatment in the delirium—blisters—Dr. Corrigan's plan—use of opium—Dr. Graves' plan of tartar emetic and opium—Treatment of hysterical delirium—Case—use of opium—restraint—Treatment of puerperal delirium—prognosis—Case.

GENTLEMEN,—I shall not occupy your time with any lengthened discussion of the mode of treatment best adapted to control the delirium which sometimes accompanies scarlet fever, measles, and other exanthemata; because I think I may state with confidence that this delirium is in all essential points the same as that of erysipelas, and that in your treatment of the former you must be guided by the same principles as would direct you in managing the latter.

I now proceed to consider the treatment of the delirium of typhus fever. In all low forms of fever delirium frequently manifests itself; and this is particularly the case in the course of typhus fever; and of typhoid fever also, if you choose to adopt the opinion of those who admit the existence of two distinct forms of disease: the one a fever of low type, characterized by a tendency to ulceration of Peyer's glands and diarrhoea—the *typhoid fever*; the other, the *true typhus*, a contagious disease, with brown tongue, great prostration, and without the tendency to diarrhoea. This is not the time to discuss the question whether two such distinct forms of fever really do exist. I must content myself with using the term typhoid delirium generically; for in both states of fever we meet with delirium of the same character, which requires the same kind of treatment, but we notice it under the two following forms:—

1st. Delirium of the low and muttering

kind, in which the patient lies on his back, constantly muttering to himself, apparently unconscious of what is going on around him, but capable of being roused by loud speaking.

2ndly. Delirium of the active kind, in which the patient is very restless, wakeful, talkative, wanting to get up, and requiring careful watching, and perhaps restraint.

When the delirium is of the active and wakeful kind, it generally comes on quite suddenly; but the low form of delirium, which is the most common, comes on very gradually, being first noticed perhaps at night as a slight wandering, then the next night becoming more marked in its characters, and afterwards continuing through both day and night.

Now delirium in fever, of whatever kind it be, is a very serious symptom, and demands the closest attention from the practitioner. Its occurrence generally denotes great depression of the vital powers, and it is of itself calculated to increase exhaustion, especially if the delirium be of the active kind.

In considering the treatment of the delirium of typhus, we shall do well to look a little into the nature of typhus fever itself, as in a former lecture I referred to the chief points in the nature of erysipelas while discussing the treatment of the delirium which accompanies that disease. Typhus fever, then, may be said to arise from the introduction into the system of a special morbid poison, capable of being generated in the human body, and of being communicated from one person to another, although possibly this may not be the only way in which the poison may be propagated. The severity of the symptoms produced by the imbibition of the poison varies much in different cases, depending upon the dose of the poison which has been imbibed, and perhaps, also, upon the condition of the patient at the time of the imbibition, and likewise upon the nature of the poison itself; for doubtless this may vary at different times, and so give rise to that variety in the nature of different epidemics to which most practical men bear testimony.

The morbid poison is eliminated from the system through certain channels, as the skin and mucous membranes; but, like the poison of erysipelas, scarlatina, and many others, it exerts an influence on the condition of the system, which is generally of a very depressing kind, and this continues until the poison is eliminated, or its influence exhausted by some change which it may undergo in the blood.

This seems to be the view of the nature of typhus fever which is most consonant with reason and experience. If it be true,

we can scarcely expect that any means we can devise will cut short the fever, or rapidly eliminate the poison from the system. We must deal with the disease as we would with erysipelas, scarlet fever, small-pox, and support our patient while the fever runs its course, guarding him as much as we can against the destructive influence of the poison. And as this poison is apt to cause great depression, the chief business of the practitioner will be to devise the best means of opposing this depressing influence. This may be best done by giving food, of a nutritious kind, in such a way as may be most easily digested, and will occasion the least irritation of the digestive organs. It will generally be found necessary to administer stimulants, and I think that it is unwise to postpone this part of the treatment long; on the contrary, I prefer giving stimulants *early*, as, by so doing, the necessity for giving them largely is generally avoided. Throughout the whole course of the fever, the greatest pains should be taken to husband the strength of the patient by good nursing, and by instant attention to every want. He should never be suffered to do anything for himself, nor allowed to get out of bed; he must be raised or turned in bed when necessary, and he must be fed as you would an infant. Too much importance cannot be attached to these apparently trivial matters in the management of so serious a malady as typhus fever. Many a patient has lost his life for want of these necessary attentions,—either from the culpable neglect of them on the part of attendants and nurses, or from his inability to obtain them.

If the bowels are confined we should give a purgative which will act very mildly, or they should be opened by enema; and, in giving medicine for the bowels, we should never lose sight of the danger there is in all these cases of the supervention of a troublesome and debilitating diarrhoea. It never can be necessary in typhus fever to purge, or to do more than keep the bowels in such an open state as will assist digestion.

In consequence of the liability of Peyer's glands to be affected with ulceration, strong purgatives may do great mischief, by increasing the inflammation, and perhaps exciting ulceration, which may end in perforation of the intestine and fatal peritonitis. On the other hand, it is very necessary to provide for the due evacuation of the intestinal canal, not only to promote the digestive powers and the due absorption of the food, but also because, if the secretions are allowed to remain in the bowels, they will themselves excite irritation, and interfere with the due elimination of the poison.

All men of experience agree that it is

right and necessary to uphold the strength in typhus fever, but differ as to the best mode of effecting this object. Some only give nutritious food, others think it necessary to combine stimulants with it. My own experience has led me to the conclusion that stimulants are necessary in the vast majority of cases. I have never seen any ill effects arise from the early administration of stimulants; and, on the other hand, I have often had occasion to regret that the use of them had been too long delayed. Moreover, this fact weighs much with me in inducing me to give stimulants early,—namely, that if a patient seem overstimulated, nothing is easier than to pull him down, and that pretty quickly; but if he be insufficiently supported and stimulated, it is often of extreme difficulty to build him up: *hic labor, hoc opus est*. And with reference to the administration of stimulants, I have only to repeat the rules which I gave you on former occasions. Do not give large quantities at a time; do not embarrass the patient, but begin with small quantities frequently repeated. Give wine first, and then, if necessary, change to brandy, or some other spirit. Chloric ether is one of the best medicinal stimulants: it may be given in half-drachm doses every three or four hours, or more frequently if necessary, alone, or in combination with five or six grains of carbonate of ammonia.

Such is a brief outline of the general plan of treatment to be pursued in typhus fever. If, now, we find that delirium sets in in the course of the fever, what is to be done? Ought this to lead us to alter in any way our mode of treatment, and to adopt new and different measures? Whatever be the nature of the delirium, we must, I think, deal with it as part and parcel of the fever, and view it as an indication of a more depressed state of the system calling for an increased amount of stimulants, or a change in the nature of them, and for greater diligence in the administration of nutritious food.

Is there any necessity for local treatment directed to the head when delirium comes on in the course of typhus fever? Nothing is more certain than that there is no inflammation of the brain in typhus fever, not even when delirium occurs: there is, therefore, no need for active local measures on this account. Some years ago a theory was put forward by a distinguished physician of this town which ascribed typhus fever to inflammation of the brain; and this gained some support from the fact that inflammation of the brain frequently takes on the characters of typhus fever, as was the case in a patient whose history I related to you in a former lecture. But the experience of nearly all practical men

in all countries tends to show that there is no connection between typhus fever and inflammation of the brain.

You will say, however, that, though there is no inflammation, there may be congestion. Undoubtedly this is the case; but the congestion is not peculiar to the brain: it is only part of a general congestion which affects the capillary system of the whole body, and is probably due to the presence of the typhus poison in the blood, which weakens the forces by which the blood is moved in that system of vessels. To relieve this congestion, therefore, ought we to resort to local depletion? Upon this point you must be guided by the circumstances of each particular case, bearing in mind that in so enfeebled a state of the capillary circulation the mere taking away of blood is seldom of much use. What is most needed under these circumstances is something to stimulate the capillary circulation, so as to promote the flow of the blood, which tends to stagnate in the fine bloodvessels. Now for this purpose the application of blisters to the shaven scalp is most useful; and you will often find it a better plan to apply several small blisters to different parts of the scalp in succession, than to apply one large one. Sometimes, however, you will not have time to wait for this process; the patient has a strong tendency to coma, or is actively delirious, and at the same time his strength is rapidly on the wane. When this is the case you must apply one large blister all over the scalp; and you will find Dr. Corrigan's plan a very good one—namely, to cut the blister plaster into strips, and to lay them over the scalp as you would strap a man's leg, so as to bring the blistering material into contact with the scalp at every point.

If you should see any clear reasons for taking away blood, you may best gain your object by having it done by expert cupping from the temples. The rapid application of the well-exhausted cupping-glass may act as a stimulus to the capillary circulation, and promote the flow of blood through it.

When the delirium is of the restless and wakeful form, are we to give opium? As a general rule, we must be extremely cautious in the use of opium in typhus fever. We know that opium tends to produce the same effects as the typhoid poison—namely, to favour capillary congestion; therefore, by giving opium, we should only aggravate one of the great evils of the typhoid state. There is another reason why opium should not be administered in fever—namely, that it tends to clog up the secretions, and so to prevent the elimination of the morbid poison, which is an object we are desirous of promoting.

Nevertheless, when the state of congestion is not obvious, and the powers of the patient are not very low, I have seen the very best effects derived from the administration of one or two doses of opium well timed.

You will often find it necessary and most useful to give opium by enema in those cases of diarrhoea which often occur in typhus, or, if you will, in typhoid fever. This is a practice which I always follow, and with the best results, never to allow the diarrhoea to get ahead, but to keep it down by the frequent administration of small enemata of starch, sometimes, if the diarrhoea be urgent, repeated twice or thrice a day, with five, ten, or twenty minims of the tincture of opium. Dr. Corrigan, who has had great experience in the treatment of fever in Dublin, states that the application of not more than two or three leeches to the temple is often of great benefit in promoting sleep; and he was first led to adopt this practice by observing that spontaneous hemorrhage from the nose was followed by sleep in some cases. Dr. Graves lays great stress upon the advantages of combining tartar emetic with opium: he says that the antimony prevents the too narcotic effects of the opium, whilst the junction of opium with antimony promotes the sedative influence of the latter, and guards the system against its depressing power.

Are we to be deterred by the occurrence of delirium from the continued use of stimulants? The mere occurrence of delirium need not deter you from the continued use of stimulants: on the contrary, in some cases it should incite you to give them more freely, in larger and more frequent doses. But in all cases their influence upon the pulse will serve you as a useful guide; and if you find that under stimulants the pulse does not quicken, but improves in quality, and more especially if it diminishes in frequency, you may continue the use of stimulants.

Hysterical delirium.—I shall now call your attention to the treatment of that form of delirium which is apt to occur in cases of hysteria—namely, hysterical delirium. A hysterical girl begins to form strange fancies: she becomes obstinate and perverse, and it is with great difficulty that she can be managed. Perhaps she may refuse to take food, and conceive a great dislike to some of her relatives, and refuses to see them. Sometimes we can detect no obvious immediate exciting cause for these symptoms beyond the existence of a chronic hysterical state; but in the great majority of cases, however, while the hysterical diathesis is present, the patients have been

exposed to some causes of depression. Such is the case with a girl of the name of Walker, now in the hospital, who is suffering from this form of delirium. She belongs to the hard-worked and ill-paid class of needle-women who have excited so much interest of late. For some time past she has been sitting at her needle for many hours a day, getting no air nor exercise, and feeding badly. She is a Roman Catholic, and an enthusiast in religion, and has been led by her religious views to practise a considerable amount of asceticism, which, in addition to her privations from poverty, have contributed much to increase her depression. In this girl there was at first no violence, but she was continually sighing, and seemed always in a melancholy mood; sometimes reciting hymns to the Virgin, at others praying fervently, imagining herself in chapel. She frequently spoke of her father and mother, without having any definite notions as to where they were, or seeming to know that one of them was dead. She could seldom be engaged in conversation, and could give no satisfactory account of herself, and she exhibited great reluctance to take food. In addition to the other causes of depression I have mentioned, she has been irregular in her catamenia; and on the last occasion, a few days before she became delirious, she had a very profuse discharge of blood, which weakened her extremely.

Sometimes patients suffering under hysterical delirium are extremely violent and mischievous, and even furious, using the most coarse and even obscene expressions. Often there is great wakefulness, which threatens to exhaust the patient.

In cases of hysterical delirium we generally meet with disturbed uterine functions; the catamenia are affected in some way, being too copious, or perhaps deficient in quantity or altered in quality; the intervals of their recurrence may be very irregular, or many months may pass without the patient having menstruated: sometimes, on the other hand, they recur too frequently. Leucorrhoea is also often present in these cases to an extent which produces extreme weakness. Under such circumstances, when a patient is exposed to privations, or from loss of appetite is unable to take food in sufficient quantity, or receives some severe mental shock, delirium is very apt to show itself. Moreover, young women, and especially those of the hysterical diathesis, are extremely apt to neglect all attention to the action of the bowels, which alone must seriously injure the general nutrition. It is not uncommon for such young women to suffer from a confined state of the bowels for many days, without exciting attention from them.

Thus, with deranged catamenia, confined bowels, irregular habits, capricious appetite, mental anxiety, often ill-regulated thoughts, and in the lower classes inadequate food and over-work, it is no wonder that a depraved nutrition should be produced sufficient to disturb the balance of the nervous system, and the due action of the mind.

In treating a case of hysterical delirium we must set ourselves diligently to discover the causes which have produced the deranged general nutrition upon which the delirium mainly depends. We must relieve constipation, without using violent means calculated to depress. If the catamenial or leucorrhœal discharge be excessive, it must be immediately checked by suitable remedies, among which, I think that the frequent use of cold water by hip baths is among the best. Careful attention must be paid to improve appetite and to help primary digestion. Hence we shall derive most benefit, generally speaking, from the combination of tonics, mineral acids, and purgatives, and sometimes from the use of chalybeates.

It is of great importance to devise some good means of administering food according to the particular circumstances of each case. As to the use of stimulants, it is difficult to lay down rules of even frequent, much less of general, application: in this part of the treatment our best guide will be derived from the peculiarities of each case: sometimes it is better to give them, and sometimes to withhold them. The state of the digestive organs, the previous habits of the patient, the effects which stimulants produce upon her, will in general afford us great help. To these I may add the rate of the pulse; a quick pulse, of 110 or upwards, indicating the need of stimulants; a slow pulse, below 90, denoting that they are not necessary. But this you must always bear in remembrance, that starvation will not answer in these cases, nor will antiphlogistic measures: such means always tend to aggravate the delirium.

In the treatment of these cases a great deal is to be done by moral means. Very frequently it is desirable that the patient should be isolated from her friends: by this I do not mean that she should be sent to a lunatic asylum; on the contrary, in a large number of instances such a course would be injurious to the patient, both at the time and subsequently. We have no more right to send a patient labouring under hysterical delirium into a lunatic establishment, than to place a patient affected with the delirium of erysipelas or of typhus there. We have no good grounds for classing these cases, more especially the

more acute ones, with ordinary cases of insanity; and we should be careful to avoid stamping a young woman with the reputation of having been once insane. The delirium in these cases is as much dependent on the disturbed state of nutrition which constitutes the hysterical state, as the peculiar delirium of erysipelas or of typhus depends upon the peculiar fever excited by the respective poisons of those maladies. The patient then, as I said, should be isolated from her friends, and be placed under the care of a kind and attentive nurse, who will keep a constant watch over her, attending carefully to her wants, and restraining her by firm but kind influence from doing what is injurious or mischievous.

Mechanical restraint is highly objectionable in the hysterical delirium, and should never be practised unless when there is an absolute necessity for it. It excites opposition, and irritates the temper of the patient often to a very serious extent. You have lately had a good opportunity of observing its injurious effects in the case of the girl up stairs. She had been treated much on the plan I have already described, with tonics, good diet, and shower bath; but she had got into the habit of wandering about from ward to ward, and the nurse was unable to control her. I directed her to be kept to her bed, and isolated from the other patients by surrounding the bed by screens. Still she could not be kept quiet; and I then allowed the nurse to tie her feet to the bed. This irritated her very much, and the next day we found her much worse, and her delirium much increased. All restraint was then removed, and since then she has been gradually improving.

The same rules which I laid down as to the employment of restraint in cases of delirium tremens, are applicable to the question of using these means in other similar cases. We must be guided by the symptoms which arise in the course of the disease, being always slow to adopt restraint.

Puerperal delirium.—I shall conclude this lecture by a brief allusion to the treatment of another form of delirium, nearly allied to the hysterical—namely, the puerperal delirium. A puerperal woman is in much the same condition as a woman affected with excessive leucorrhœa, or with any other exhausting disease tending to deteriorate the general health. She is exhausted by the efforts of parturition, or her vital powers are depressed by some condition consequent on the puerperal state.

When speaking of hysterical delirium, I omitted to mention that there are two classes, differing from each other in their results.

1. A class of cases in which the pulse is very quick, varying from 120 to 140.

2. Cases in which the pulse is usually below a hundred.

In these two classes the prognosis is very different. If the pulse be quick, and continue quick despite of support, stimulants, and tonics, the prognosis is in general unfavourable; on the other hand, if it be below 100, and show no tendency to become rapid, the case may be looked at more favourably. By far the greater number of the cases of hysterical delirium belong to this latter class, and by far the greater number get well. Now it is just the same with puerperal delirium. We find two classes of cases distinguished by the difference in the rapidity of the pulse, and which affords the same prognostic indications as in hysterical delirium. The existence of these two states of pulse in puerperal delirium was long ago pointed out by Wm. Hunter and by Gooch.

The general treatment of puerperal delirium must be conducted on much the same plan as that which I have laid down for the hysterical. Almost always some exhausting influence has been in operation, or there has been some severe mental shock. You must combine a soothing and strengthening treatment with moral management, and remove as far as possible all causes of mental excitement, as well as of bodily depression.

When you have to deal with a case in which the pulse is extremely rapid, you will generally find it necessary to be very diligent in the use of stimulants and of nutritious food; and indeed your ultimate success in the treatment of the case will much depend on your patient's ability to digest and assimilate these aliments.

We had a good example of the good effects of this treatment in a case of this kind of delirium, which occurred in the hospital last November. The patient's name was Mary Tilley, and she was only twenty years of age. Although in this case the pulse reached the high number of 160, and continued at that rate every day, accompanied by extreme debility, the patient did well. The delirium had been brought on by excessive hæmorrhage after parturition. The patient stated that on the third day after the birth of the child she passed something as large as a child's head, having the appearance of black currant jelly—a tolerably good description of a large clot of blood: this was followed by suppression of the lochia, great prostration, and delirium. When she was admitted, the tongue was covered with a brown fur; she was delirious, talked very much in her sleep, and frequently jumped out of bed, and exhibited a certain strangeness and wildness of

manner; her pulse was 160, and the respiration 40. She was placed upon a freely stimulating treatment, with ammonia, and wine, and beef-tea; for several days she took half an ounce of wine every hour. On her admission the pulse was 160, and respiration 40; the next day it had not diminished in frequency: during these days she was taking half an ounce of wine every hour. On the 14th (the third day after admission) the pulse fell to 130, but the delirium continued. She was sleepless; talked a great deal, and fancied some one was coming to take her away and kill her. The quantity was now increased to an ounce every hour. On the 17th (the sixth day after admission) she was reported to have slept well, and the delirium had considerably subsided. The pulse, however, was still 130. On the 19th she had improved still further, and the pulse had fallen to 120. I now gave her quinine (the tongue having become clean) in doses of two grains every fourth hour. On the 20th the pulse was 108. The quantity of stimulants was now gradually diminished, and on the 8th of December the pulse had fallen to 88, and from this time she rapidly convalesced.

You must deal with these cases of puerperal delirium in much the same way as you deal with cases of erysipelas or typhoid delirium, because in all these conditions the patient suffers from a state of exhaustion detrimental to general nutrition. In puerperal delirium, however, we may give opium with great safety: in violent cases, in which sleep could not otherwise be procured, I should not object to administer chloroform, bearing in mind the cautions to be observed during and after its inhalation, which I mentioned in a former lecture.

It remains for me to discuss the treatment of the epileptic delirium: this, with some remarks on the treatment of the various forms of coma, I propose shall form the subject of my next lecture.

ELECTION OF PRESIDENT AT THE ROYAL COLLEGE OF SURGEONS.

At a meeting of the council of this institution on the 11th inst., Mr. James Moncrieff Arnott, F.R.S., was elected president, in the vacancy occasioned by the retirement of Professor Joseph Henry Green, F.R.S., who, it is stated, has during the past year filled the high position with a dignity, and at the same time an amiability, never surpassed. Messrs. John Flint South, of St. Thomas's Hospital, and Caesar Henry Hawkins, of St. George's Hospital, were elected vice-presidents of the College for the ensuing year. At the same meeting of the council Messrs. Pilcher, Macnirdo, and Kiernan, the recently elected members, took their seats at the board.

Reviews.

Anormal Nutrition in the Human Articular Cartilages, with Experimental Researches on the Lower Animals. By P. REDFERN, M.D., London, Lecturer on Anatomy and Physiology, and on Histology; and Examiner at the University and King's College, Aberdeen, &c. &c. Pamphlet, 8vo. pp. 86. (From the Edinburgh Monthly Journal of the Medical Sciences.) Edinburgh: Sutherland and Knox. London: Simpkin and Co. 1850.

"PERHAPS there is no tissue," the author remarks, "which affords a better opportunity for the examination of many of the changes which nucleated cells undergo, in the different periods of their existence, than that of cartilage; for in it, changes which take place at certain periods only in other textures, are continually going on during the whole life. Moreover, these changes in the articular cartilages in man are effected without any more direct communication with blood-vessels than that which exists upon their surfaces; for it is only when such cartilages exceed a certain thickness—i. e. about 1-8th of an inch, that they are permeated by canals which contain blood-vessels, as occurs in the large mammals."

Dr. Redfern refers to the researches of Drs. Alison and Bennett, showing that inflammation consists in a peculiar perversion of nutrition or of secretion, and "that all the changes that take place in the matters exuded in inflammation, are alone referable to the general plan by which the nutrition of the healthy textures is effected." (p. 6.)

The author then proceeds to observe—

"That changes, which may be equally referred to an abnormal nutrition of the textures, take place in the diseases to which articular cartilages are so liable, appears plain from the nature of the changes that occur in them in such cases, and which I shall endeavour to describe and illustrate as they appeared to me during lengthened examinations of a number of cases, the particulars of which will be afterwards detailed.

"It is said that inflammation, ulceration, softening, hypertrophy, atrophy, and ossification, are the diseases to which cartilages are liable. Of the existence of inflammation in them there is perhaps no other evi-

dence than that furnished by ulceration, which is unquestionably the most important of all the affections of this texture, and is generally believed to be the climax of the most severe affections of the joints." (p. 6.)

Dr. Redfern briefly reviews the most important of the opinions that have been advanced on the nature of ulceration of the cartilages.

In the next place, the author details a series of cases, and illustrates his examination of the diseased cartilages, in almost every instance, by several well-executed wood-engravings of the microscopical characters of these morbid structures. The fulness of the observations, and their accompanying remarks, with the abundance of illustrative drawings, constitute the essential value of Dr. Redfern's work, which, we think it no slight praise to say, may be compared, in these respects, so far as it extends, with Dr. Bennett's work on Cancerous and Canceroid Disease.

Dr. Redfern devotes also a portion of his work to the consideration of the healthy structure and mode of nutrition, before treating of the affections to which the articular cartilages are liable: these are discussed under the heads of Morbid Anatomy, Chemistry, Pathology, Diagnosis, and Treatment. We quote the author's conclusions, deduced from his previous observations and examinations.

"1st. That the whole of the known forms of disease in articular cartilages are connected with changes in the texture, which are essentially similar to each other.

2d. That during the progress of these changes the cells of the cartilage become enlarged, rounded, and filled with corpuscles, in lieu of healthy cells, bursting subsequently, and discharging their contents into the texture on the surface; whilst the hyaline substance splits into bands and fibres, the changed hyaline substance and the discharged corpuscles of the cells afterwards forming, in many cases, a fibro-nucleated membrane on the surface of the diseased cartilage.

3rd. That these changes are alone referable to an abnormal nutrition as their immediate cause, and in no case to mechanical or chemical action,—such as attrition or digestion in a diseased secretion.

4th. That most extensive disease may be going on in many joints at the same time, and may proceed to destroy the whole thickness of the cartilage in particular parts, without the patient's knowledge, and

while he is engaged in an active occupation.

6th. That the disease commences most frequently upon the free surface; but it may proceed from the bone to affect the attached surface, or it may take place in the middle of the thickness of the cartilage.

6th. That it is at least very doubtful if the symptoms, which are believed to indicate the existence of ulceration of articular cartilages, are not really dependent on a morbid change in the bone.

7th. That disease of the whole thickness of an articular cartilage, at particular parts, admits of a natural cure, by the formation of a fibro-nucleated membrane from the substance of the cartilage, without the occurrence of any new exudation." (p. 65).

The importance and value of Dr. Redfern's investigations will be apparent from the nature of the above conclusions, more especially when taken in connection with a series of comparative experiments on lower animals, instituted by Dr. Redfern, whereby these conclusions are confirmed. The results in the last cases are similar to those observed in analogous diseases of cartilage in man. On a subject on which such diversities of opinion have been held as on ulceration and other diseases of the cartilages, it is something to have a series of trustworthy facts carefully recorded by a competent observer. These will be found in Dr. Redfern's work; and we therefore press its study upon every pathologist.

Proceedings of Societies.

NEWCASTLE AND GATESHEAD PATHOLOGICAL SOCIETY.

February, 1850.

Case of Diseased Bladder, with Formation of a large Sac containing numerous Calculi, and communicating through a comparatively small aperture with the general cavity of the viscus.

In this interesting case the bladder consisted of two sacs communicating by a small aperture, the posterior sac being filled with calculi. The man was 36 years old, and broken down by dissipated habits. He was first admitted into the Newcastle Infirmary, under Sir John Fife, in May 1849, with some secondary ulcerations of the legs; he never complained of any urinary disorder until about a month after his admission, when re-

tention of urine suddenly took place; a catheter was with great difficulty introduced by one of the pupils, much blood having been lost, with some suspicions that a false passage had been formed; there was no stricture, nor any other cause to account for the retention. The ulcers on his legs were at this time nearly healed, when severe inflammation of the bladder, extending to the pelvis of the kidney, set in, and he remained in the hospital during three months: he at first required the catheter twice daily, but gradually acquired the power of dispensing with it after the severity of the attack passed away. Along with the acute symptoms, the urine presented a highly ammoniacal and purulent character, which changed to a slightly albuminous condition, depositing a thin layer of pus, and frequently very copious and of a light green colour. When he left the hospital he had recovered his health to a great extent; but still passed urine slightly purulent and albuminous. He was re-admitted under Mr. Heath four months afterwards, and was now found to be weak and wasted, with hectic fever, the result of great accompanying urinary irritation, together with a copious excretion of purulent urine, occasionally mixed with blood. He frequently required the use of the catheter; and, except the difficulty experienced in avoiding the aperture of a false passage at the membranous part of the urethra, nothing could ever be found in the bladder. He died exhausted on the 13th of February, 1850. On opening the abdomen the bladder was seen to be firmly contracted, empty, and in its natural position; projecting from it behind was a large sac of the rounded form of a moderate-sized orange, pressing back upon the rectum and filling the pelvis. The urethra and bladder were laid open. The floor of the membranous part of the urethra presented the open mouths of several enlarged lacunae, and immediately in front of the prostate, a smooth slit-like opening, allowing a No. 10 sound to pass into a small false passage, running behind the prostate, and terminating about an inch above it in the coats of the bladder. The muscular coat of the bladder was greatly hypertrophied; the mucous membrane, thickened, congested, and covered with a purulent layer of mucus, was not ulcerated; at its posterior aspect there was a round aperture of the size of a florin piece, leading into the cavity of the sacculated dilatation of the viscus: the margin of the aperture was rounded, nearly half an inch thick, slightly extensible, and consisted of the hypertrophied muscular fibres of the bladder, covered by the thickened mucous membrane. The sac was filled with purulent urine, and about forty calculi, composed of triple phosphate; the largest set being about the

size of hazel-nuts; the others gradually diminishing until they formed a coarse powder, which was mixed with coagulated blood. The wall of the sac was about 3 lines thick, and consisted of the mucous membrane bound to the peritoneum by lymph and a fibrous kind of cellular tissue: no muscular tissue was found in it.

The ureters and pelvis of the kidneys were considerably dilated; the mucous membrane thickened, congested, and secreting purulent fluid. The secreting structure of the kidney was coarse and flabby; but not otherwise diseased. The other viscera comparatively healthy.

This case is highly interesting and instructive, whether considered with reference to the diagnosis of stone in the bladder, or the practical difficulties occasionally met with in the performance of the operation of lithotomy. None of the symptoms ordinarily relied on as pathognomonic of the existence of a calculus, were here presented, nor did even the passage of a catheter into the bladder lead to the detection of the numerous calculi existing in the posterior sac of that viscus. They would, however, probably have been perceptible by a finger introduced into the rectum; and the history of the present case may perhaps be received as an additional illustration of the importance of instituting such an examination in doubtful cases.

But assuming the calculi to have been detected by the catheter or sound of the surgeon, and the operation of lithotomy to have been undertaken by the latter, how vast and inextricable the difficulties and confusion opposed to his success! On completing the requisite incisions, and passing his finger into the bladder, the surgeon would have felt in vain for the stone, whilst an examination per rectum, performed immediately afterwards, would have satisfied him of the existence of several calculi in the posterior part of the same bladder.

Under these perplexing circumstances he could only have chosen between the unpleasantness of allowing his patient to return to bed with the calculi unremoved, and the certain danger consequent on any attempts to divide the septum which intervened between the pouch containing the mass of calculi and the general cavity of the bladder.

Conversion of a Diseased Kidney into an immense sac, without any perceptible symptoms during life.

Dr. BULMAN communicated the subjoined particulars of this case, which occurred in a seaman aged 26, who awoke one morning with partial hemiplegia of the left side, and after becoming gradually worse, entered the hospital, under Dr. B., in November, 1849, five weeks after the attack. His symptoms

indicated softening of the brain; and after a course of mercury and counter-irritation for one month without any improvement, he died of a most rapid and uncontrollable pleuritis. He had never once complained of any symptom indicating any affection of the kidney.

On examination of the brain, the right corpus striatum was found almost entirely converted into a soft, greasy, pultaceous mass, containing numberless exudation cells of varied size and form. The left pleural sac was filled with semi-purulent fluid, and covered with false membrane. The left kidney, occupying the whole of the left loin, and extending across the spine, was converted into an immense membranous sac, similar in structure to the fibrous pelvis of the kidney, and filled with nearly a quart of slightly turbid, but otherwise healthy urine. Slight remains of very pale secreting structure were observable in the outer and posterior aspect of the walls of the sac. The ureter was found perfectly healthy; but its opening into the pelvis of the kidney was so small, that the head of a probe was with difficulty pushed through it into the great sac occupying the place of the kidney and its pelvis. There was no induration or hypertrophy of tissue around this narrow opening, which appeared to have been gradually contracting during a very long period, but on the contrary the usual healthy tissue of the ureter. The other kidney was very large, lobulated, and of healthy appearance.

Osteo-sarcoma of Tibia and Fibula.

SIR JOHN FIFE exhibited a beautiful specimen of osteo-sarcoma of the lower ends of the right tibia and fibula, removed by amputation of the leg from a countryman, aged 17, whose family were highly scrofulous, and who was admitted into the infirmary. He had first observed a little general swelling above the ankle six months previously, which rapidly increased, accompanied with little pain, and now formed a large and characteristic tumor immediately above the ankle-joint. There was no glandular disease. He quickly recovered from the operation, and was sent home in a greatly improved state of health. The tumor on being cut open presented the brain-like appearance of medullary cancer, with vascular tufts of fungus hæmatodes and numerous spicules of bone radiating from the enlarged tibia and fibula, which were implicated in the diseased growth. Microscopically, the tumor was composed entirely of cells of rounded or ovate form, of varying sizes, and highly organised; the cell walls being covered with numerous small nuclei refracting the light very powerfully.

ACADEMY OF MEDICINE, PARIS.

July 2nd, 1850.

Epidemic Dysentery of Mortagne in 1849, and its Relations to Epidemic Cholera.

M. GIBARDIN read a report on a paper by M. Hullin, of Mortagne. It was stated that in 1832, when cholera prevailed in the district adjoining Mortagne, that place was spared, an epidemic dysentery prevailing there at the time. The same circumstances had occurred in 1849.

The Alkalinity of the Human Blood.

M. CAHEN read a memoir, in which he sought to establish that albumen and fibrine are held in solution by virtue of the alkalinity of the serum: a decrease in the alkalinity of the serum augmenting the proportion of spontaneously coagulable albumen, and *vice versa*. The author laid down these conclusions.

On the healthy state.—1. The serum holds in solution a substance, which ultimately separates the albumen and fibrine. 2. The albumen and fibrine are susceptible of mutual transformation. 3. Fibrine is converted into a substance not distinguishable from albumen, by a solution of soda at the temperature of 106° F.

In inflammatory diseases.—1. Fibrine is increased, albumen decreased. 2. The salts of soda are deficient. 3. The serum is deficient in alkalinity. 4. The increase of fibrine is owing to the diminution of the alkalinity of the serum.

In diseases called putrid, the alkalinity of the serum causes diminution of fibrine, and indicates the use of acids in treatment.

SURGICAL SOCIETY OF PARIS.

July 3rd, 1850.

Reduction of long-standing Dislocation.

M. MAISONNEUVE related the particulars of a case of dislocation of the humerus under the *pectoralis*, in which many fruitless efforts at reduction had been made by M. Velpeau, and in which he, M. Maisonneuve, had succeeded by longitudinal traction continued for ten minutes, chloroform having been administered. M. Maisonneuve added, that in his opinion the adhesions, &c. of old dislocations could always be overcome.

M. CHASSAIGNAC observed that the proceeding adopted by M. Maisonneuve, after the failure of so skilful a surgeon as M. Velpeau, was somewhat hazardous. The employment of anæsthetics in such cases,

the patient being in the upright posture, M. Chassaignac considered to be attended with danger. In long-standing cases he also thought the use of anæsthetics to be contraindicated, as the resistance did not proceed from the muscles alone. M. Chassaignac expressed his surprise that the heel of the operator is not used in France, so much as its success in England shows it to merit, in reducing dislocation of the shoulder.

M. MOREL pointed out the dangers which attend the attempt to reduce long-standing dislocations; and observed that the insensibility produced by anæsthetics deprived the operator of the indications furnished by the feelings of the patient as to how far the extension may be carried.

M. FORGET concurred in the objections to the violence necessary in reducing old dislocations; and, more particularly with regard to the use of anæsthetics, observed that in proportion to the length of time required for the reduction were the dangers of anæsthetics increased by their lengthened employment.

M. MAISONNEUVE did not participate in the fears of other members, and thought that all dangers might be avoided by great care.

ACADEMY OF SCIENCES, PARIS.

July 1, 1850.

Staphyloraphy.

M. ROUX read an essay of considerable length on this subject, of which the following are the chief points:—

M. Roux divided the lesions for which this operation is required into four kinds—the recent accidental; the congenital; the surgical; and the old accidental, or ulcerated and cicatrised solutions of continuity. The operation is modified according to the character of the lesion. 1. A complete cleft in the velum, not implicating the palatine arch; 2. A simple perforation of the velum; 3. A perforation of the arch not extending to the velum. The term staphyloraphy is strictly applicable to the two first only: the last should be designated *palatoplastie*.

M. Roux related cases of these various kinds in which he had operated successfully, and pointed out at the same time their causes—syphilis, tubercle, &c. &c. M. Roux had performed staphyloraphy on one hundred and six subjects; in nine of these a second time, making a hundred and fifteen cases: of these individuals 57 had simple fissure of the velum and uvula; 49 had also fissure of the palatine arch. The

particular features of the result of the operation in many of these cases were also stated by M. Roux. For these details, however, we must refer our readers to the *Comptes Rendus* of the Academy, or to the French journals, our space preventing a more extended report.

Hospital and Infirmary Reports.

LONDON HOSPITAL.

Case of Dislocation of the Thigh into the Foramen Ovale, reduced after four weeks. With Clinical Remarks by JOHN ADAMS, Esq., Surgeon to the Hospital.

JAMES COE, *etat.* 32, a strong muscular man, employed as a navigator on a railway, was admitted on Tuesday, May 28th, with a dislocation of the thigh into the thyroid foramen; the accident having occurred a month previously, in the country, in consequence of the fall of a large quantity of gravel into the left slip, while he was in a stooping posture, with his legs widely separated. He was extricated by his fellow-workmen, being unable to move himself: and on examination, was found to have sustained severe laceration of the perineum and scrotum. Considerable swelling and extravasation ensued, and he was confined to his bed 20 days, the ordinary surgical appliances being resorted to by his medical attendant, and upon the subsidence of the swelling and tumefaction, and the healing of the lacerations, it was then discovered that the left thigh-bone was dislocated from the acetabulum into the foramen ovale: attempts at reduction were then made, and repeated on the following day, under the influence of chloroform; but, as no success resulted, he was sent up to the hospital, and placed under the care of Mr. Adams, who made a careful examination of the limb, with the following results:—The patient was lying in a supine position, with the left limb widely separated from the right, at a distance of nearly seven inches, the corresponding knee being considerably elevated in advance of that on the sound side: complete adduction was quite impossible, although the limb could be drawn considerably towards the axis of the body, but immediately on remitting the pressure it resumed its former position with considerable elasticity: the foot and toes were slightly everted: there was a remarkable sinking of the hip, so that the trochanter major was barely perceptible, and a considerable hardened swelling was evident

close to the pubis, beneath the adductor muscles. From the position of the limb, and other appearances, it was at once inferred, that the head of the bone was in the foramen ovale; some doubts, however, were entertained on the subject, from this circumstance, that on measuring the limb, from the spine of the ileum to the inner malleolus, and comparing it with the sound side, no actual lengthening was apparent; indeed, by some surgeons present, there was considered to be evidence of a slight amount of shortening. On placing the patient in the erect posture, at the side of his bed, the ordinary signs of displacement into the foramen ovale were rendered quite evident. Dissatisfied with the usual mode of measurement, as presenting an anomaly in this case, Mr. Adams found that when one end of the tape was applied to the dorsum of the penis close to the pubis, and was carried down to the base of the patella, there was an absolute elongation of nearly two inches. In consequence of the excoriations, resulting from the previous attempts at reduction not being quite healed, and at the urgent request of the patient for a slight respite, Mr. Adams postponed any further attempts for a couple of days: at the expiration of that period, the patient was brought into the operating theatre, and placed on his back upon a sofa, the pelvis being brought as near as possible to the edge, with a padded post directed close against the left side of the perineum: a jack towel was then applied above the knee of the dislocated limb, to which the hook of the pulleys was attached, and counter-extension was effected by a broad towel, passed under both ilia, and secured by assistants on the opposite side, with a view alone of affording complete relaxation of all opposing muscular force: chloroform was administered, and when the patient had become completely under its influence, the extension was commenced in a direction obliquely across the lower third of the sound thigh, the post forming a fulcrum, around which the upper part of the thigh was drawn, and by which movement it was hoped the head of the bone would be tilted into the acetabulum: to prevent the possibility of its slipping beneath that cavity into the sciatic notch, great care was taken during the continuance of the extension that the shaft of the bone was not raised above the level of the sound limb. Much difficulty was experienced in keeping the pelvis perfectly in the horizontal position and uninfluenced by the extending force, but this difficulty was with care effectually counteracted by the assistants. During the first attempt at reduction the man was sitting up and directed to embrace

the post firmly, but in consequence of the difficulty experienced in maintaining that position, he was, as just stated, placed in the horizontal position, whereby also the full effects of the chloroform could be more efficiently maintained: he was subsequently raised again to the sitting posture, (the extension still being continued) when on examination it was believed that the head of the bone had resumed its natural position: all extension was then immediately remitted, and as there was still some little doubt upon the subject, the lower end of the thigh-bone was carried suddenly as far as possible across the sound limb, and all apparatus being removed, it was found, on measurement, that the limb was reduced; the legs were then tied together, and the patient put to bed. The force employed during the extension did not cause any fresh accession of inflammation about the parts, neither did he suffer from any constitutional irritation, but he was kept as much as possible motionless, until eight days after the reduction, when the bandage, which had been carefully retained, was removed, and the limb was found to have a perfectly normal aspect; he was then ordered to rub it night and morning with soap liniment, and to take an occasional dose of aperient medicine. Three days after the bandage was removed from his knees, he was allowed to sit up daily in the semi-recumbent posture, which he continued to do for a week, and at the end of that period, no untoward symptoms having arisen, he was ordered a pair of crutches and directed to get up every day, and gradually bring the leg into use. To-day, (June 21st) which is just three weeks after the reduction, and seven weeks from the original accident, the man is able to walk the length of the ward, and to bear considerable weight upon the dislocated limb with no inconvenience, and his health has in no way suffered from the necessary confinement which he has sustained: he will evidently be discharged from the hospital in a few days, cured. (For the particulars of the above case we are indebted to the notes of Mr. Thomas Bell, the patient's dresser.)

Upon the circumstances attending the above case, the following clinical observations were offered by Mr. Adams:—

Gentlemen,—I am anxious to make a few remarks on this very important case, as there are some circumstances connected with it which require explanation, and especially as such cases are not of very common occurrence. Some years ago, I remember well that four dislocations of the hip into the foramen ovale were admitted into this hospital within the space of

twelve months, but since that period not more than two or three have been admitted, and the four cases to which I allude were all reduced in the same manner, and I may add with comparative facility. In the first case, which was admitted at the time I now speak of, extension was made unsuccessfully, and the surgeon who had the management of the case surrendered it as in his opinion irremediable, when, by the adoption of a plan similar to that you have just seen put into execution, the dislocation was reduced with comparative ease. Let me, however, briefly allude to the circumstances connected with the case before us, as there are some apparently anomalous symptoms which I am anxious to explain to you, and which I think I can do satisfactorily. The man is brought to the hospital a month after the occurrence of the accident, with most of the ordinary signs of dislocation into the thyroid foramen, the accident also having been caused by a fall of earth upon the left hip, while his legs were widely separated (I mention this particularly, because it is the usual position to favour the occurrence of this variety of displacement of the head of the thigh-bone). It appears that in consequence of an extensive laceration of the perineum and scrotum, together with the great tumefaction of the parts about the pelvis and hip, the nature of the accident could not be accurately made out, but after the lapse of four weeks, on the discovery of the dislocation, forcible extension was made on two separate occasions (the last while the patient was under the influence of chloroform) but without success. The man was therefore sent up to the hospital by the medical men in the country, and the symptoms, as already described, were sufficiently evident as indicative of a dislocation of the hip into the thyroid foramen, the only discrepancy arising from the fact that so far from their being any considerable lengthening, (as ascertained by measurement from the usual points) the dislocated limb was found certainly to be not longer than the sound one; and it is to that point I now wish to direct your special attention. If you will refer to the work of our great authority on Dislocations, Sir Astley Cooper, you will find, in that portion devoted to the account of this variety of the luxation of the hip, that after having described the usual cause of this accident (which, by the way, fully corresponds with the account given by the patient in the present case) and having related the peculiar appearances as indicative of this dislocation, he concludes with the following important review of the previously described symptoms. "The foot, though widely separated from the

other, is generally neither turned inwards nor outwards, although I have seen it varying a little in this respect, in different instances; *but the position of the foot does not, in this case, mark the accident. The bent position of the body, the separated knees, and the increased length of the limb, are the diagnostic symptoms.*" Now all these appearances were, in this case, found to obtain, and were very evident, except the increased length of the extremity, and I think a sufficient explanation of this fact can be afforded in the following manner: in the first place, you will observe that if a line be drawn from the anterior superior spinous process of the ileum to the base of the patella, it represents one side or base of a triangle, of which the other two sides are represented, the first, by a line drawn from the anterior superior spinous process of the ileum to the trochanter major of the femur, and the other from the trochanter to the patella. Now it is of course a well-known mathematical axiom, that any two sides of a triangle are greater than a third; therefore, the line which would, as previously stated, represent the base, will be less than the other two lines which converge at the trochanter; but as the foramen ovale is in a plane below and internal to that of the acetabulum, it follows that, when the head of the bone is thrown on to that aperture, the whole axis of the shaft is changed, the lower extremity having necessarily an inclination outwards and forwards, varying in degree, (as regards the latter particular) in different cases; the apparent lengthening being in an inverse proportion to the degree of advancement: now, from the position which the axis of the bone follows when dislocated, it is quite manifest that the bone falling from the spine of the ileum to the patella would be actually diminished, and the converging angle at the patella would be proportionately more acute. As all authors who have written on the subject of this dislocation have described the spine of the ileum as the point from which the line of measurement should be taken, and as the adoption of that plan in this particular case would not indicate the most diagnostic symptom of the accident, I conceived that this apparent anomaly might be satisfactorily explained, by assuming that the spine of the ileum was here more depressed than usual, on account of the very great tension and contraction of the abductors of the thigh, and that if some intermediate point was substituted which did not vary its relative position with the two sides of the pelvis, any actual alteration of the limb in length would be clearly indicated in the

result. Now such a point is to be found in the symphysis pubis, and would be represented in the living subject by a line passing along the centre of the dorsum of the penis: I therefore applied one end of the tape to this point, and then ascertained, as I expected, that the distance intervening between it and the base of the patella was increased by two inches when compared with the sound side.

Permit me now to refer to the treatment adopted in this case, and which I consider requisite to be pursued under similar circumstances. If we look to the position of the parts about the pelvis, we shall find that the head of the bone is depressed into the foramen ovale, and that the glutæi muscles, the powerful extensors of the limb, are principally put on the stretch: but perhaps I shall better explain the condition of the parts by referring you to the account of the dissection of a similar case, given by Sir Astley Cooper, in his work on Dislocations. At p. 66, he writes:—"The head of the bone was found resting on the foramen ovale; but the obdurator externus muscle was completely absorbed, as well as the ligament naturally occupying the foramen ovale now entirely filled by bone. Around the foramen ovale bony matter was deposited, so as to form a deep cup, in which the head of the thigh-bone was enclosed, but in such a manner as to allow of considerable motion; and the cup thus formed surrounded the neck of the thigh-bone without touching it, and so inclosed its head that it could not be removed from its socket without breaking its edges. The inner side of this new cup was extremely smooth, not having the least osseous projection at any part to impede the motion of the head of the bone, which was only restrained by the muscles from extensive movements. The original acetabulum was half filled by bone, so that it could not have received the head of the thigh-bone if it had been put back into its natural situation. The head of the thigh-bone was very little altered; its articular cartilage still remained; *the ligamentum teres was entirely broken*, and the capsular ligament partially torn through. The pectoralis and adductor brevis had been lacerated, but united by tendon; the psoas and iliacus internus, glutæi, and pyriformis, were all upon the stretch."

Now what I wish especially to observe is, that in the case just related, the ligamentum teres had been completely ruptured, as this kind of dislocation is said by some to be the only one in which that ligament remains intact; and to prove to you that modern authors of considerable experience do not consider this as an inevitable conse-

quence of this accident. I need only quote an observation of Chelius, from his *System of Surgery*, where, at p. 795, vol. i., he says:—"The capsule, as well as the round ligament, is torn in every one of these dislocations, though in that inwards and downwards it may remain entire." As regards the treatment necessary to be adopted in dislocations of this description, with whatever force you apply extension, unless that extension be used in a right direction, your efforts at reduction will be totally unavailing. And you must remember, in these cases, especially when the bone has been out of its socket for four or five weeks, that muscular action will assist you but little in drawing the head of the bone into its natural position; and that you must not expect, in the return of the bone into its original socket, any evidence of such an occurrence by the jerk or click, which is so characteristic of reduction in a recent case. The great object in the reduction of a dislocation from the foramen ovale is to apply a fulcrum to the upper part of the thigh-bone; then, using the limb as the long arm of a lever, and drawing it inwards, forcibly to thrust out the superior third of the bone, by which means the head is restored to its natural position in the acetabulum without any extraordinary extension of the limb. Sir Astley Cooper advises that you should apply a girth or band (after fixing the pelvis) to the upper third of the thigh, and, drawing it outwards, it should be fixed to a staple in the wall, and that the surgeon, then grasping the ankle with his hand, should draw the limb inwards behind the opposite leg. But the most simple and effectual method is to make a fulcrum with a pillar or bed-post, or any other similar contrivance (which, I believe, was first recommended by Mr. Hey, of Leeds), and draw the limb around it, by which the head of the bone is tilted up, and the reduction easily accomplished. Owing to the lapse of time since the occurrence of the accident in the present case, we naturally anticipated unusual difficulties: but I always had an impression in my mind that this dislocation might be reduced, as I was convinced that muscular action was not the sole antagonistic power, and that if extension were made in the right direction reduction might be accomplished. And I think I am justified in saying that no extraordinary exertions were used in this case, and that the restoration of the limb was due rather to the correct application of power than to any violent extension. (Mr. Adams here exhibited the cast of a preparation, displaying an unreduced dislocation of the head of the thigh-bone

into the foramen ovale, where a new socket had been formed by a deposition of bone round the edge of the foramen ovale, forming a complete acetabulum.)

The above remarks concerning the peculiarities attending this case will be easily understood on reference to the following diagram, which has since been suggested to us by Mr. Wyatt, the late house-surgeon, for the purpose of demonstrating the alteration in the axis of the bone in this variety of dislocation, and the effects thereby produced on the usual points of measurement, as seen below:—

He assumes that the lower extremity of the shaft of the femur, during its normal movements, describes part of the circumference of a circle, the centre of which is represented by the head of the bone in the acetabulum; and that a horizontal line, passing through the entire pelvis on a level with the crest of the pubis, would pass through the centre of the acetabulum, and also divide the imaginary circle into two equal portions. That line is represented in the diagram by the symbol A: another horizontal line, on a lower plane B, passes through the centre of the foramen ovale (c), while the upper line CC' indicates the level of the anterior superior spinous of the ilia. (a) represents the acetabulum, with a line passing in the normal inclination of the thigh-bone; and D another, which, passing through the centre of the symphysis pubis (b), indicates the central axis of the body. P represents the normal position of the base of the patella; therefore aP would indicate a line passing through the central axis of the femur, and bPC the normal angle produced by the convergence of the lines drawn respectively from the superior spinous process of the ileum and crest of the pubis. Now, when the head of the bone is shifted from (a) to (c), or the foramen ovale, cP' will represent the axis of the femur in the abnormal position; and, although the lines cP' and aP must necessarily be equal, yet it is quite evident that the dotted line CP' must be less than the line CP, and that the dotted line bP

will be greater than the line δP . In consequence of the point (e) being a plane below that of the point (a), it follows that the lower extremity of the line cP' being thrown away from the perpendicular axis of the body, the point P' will approach nearer the point O , and therefore will be further removed from the central point δ . And these conclusions are found accurately to obtain on the skeleton on the following proportions :—

$CP = 21$ inches, and $\delta P = 17$ inches ;
 $CP' = 21$ " and $\delta P' = 19$ "

Upon consideration of these facts, it would naturally be inferred, that in every case of this species of displacement no actual lengthening of the limb could be ascertained to exist between the spinous process of the ileum and patella, because lines drawn from fixed points can never vary, and that could not obtain, except when distortion of the pelvis existed. He believes, therefore, that the discrepancy arises from the oblique position of that side of the pelvis, and also from the peculiar inclination of the limb (when dialocated) ; which certainly does then *assume* an aspect of apparent elongation between the points CP' , but not between the points δP , where an actual lengthening must invariably exist.

Correspondence.

THE CASE OF MR. DYCE SOMBRE.

SIR,—It will be in your remembrance that the case of Mr. Dyce Sombre received a long hearing from the Lord Chancellor, in the spring of 1849.

In the course of his elaborate and careful judgment, it fell in with his Lordship's views respecting this important case to animadvert on doctrines laid down in a report, addressed to the Lord Chancellor by the President of the College of Physicians, Sir Alexander Morison, Dr. Copland, Dr. Ferguson, Dr. Costello, and myself. Whatever our opinion might be of the estimate of these doctrines formed by his Lordship, of the extent to which they might require modification, or the clearness with which they had been propounded by us, we considered our duties at an end, when we had sent in our report to Mr. Dyce Sombre's solicitor ; and we abstained from comment. A publication has, however, since taken place, in one large volume, of all the documents adduced under the charge of lunacy, brought against Mr. Dyce Sombre, from the commencement of these proceedings to the present time.

As this book may be widely circulated, it seems desirable that as much light should be thrown, as the subject will afford, on the apparently conflicting principles contained in our report to the Lord Chancellor, and his Lordship's judgment on the case.

The subject in regard to which the public has to be defended against misconceptions is mainly involved in the following extracts—one from our report, the other from the judgment of Lord Cottenham: and however appreciated that principle may have been by his Lordship, we must, I think, admit that it has not been sufficiently developed by ourselves or by the learned counsel who argued the case. The passage in our report, after some discussion of the circumstances under which one special delusion in Mr. Dyce Sombre's mind appeared to have been formed, the only one which still appeared to us to hold possession of his mind, proceeds as follows: "It entirely falls in with our experience, that a delusion thus formed and thus strengthened should survive the insane state; and we are of opinion, that we should act with very great injustice if we should consign a patient to a mad-house on the ground of his asserting one morbid impression, when the whole context of his character indicates sanity. On this passage, Lord Cottenham animadverts as follows—"When physicians tell me, that delusion is not inconsistent with a sound state of mind, I cannot help believing that they regard delusion as a separate disease; whereas it has always been held to be the result of unsoundness of mind; the symptom merely of the disease, and not the disease itself. The delusion may exhibit itself more or less; but, so long as it exists at all, there must be some unsoundness of mind. When they tell me, that notwithstanding there is delusion the mind is sound, they appear to involve themselves in a contradiction."

It must certainly be admitted, that the proof of mental unsoundness does not rest exclusively on the proof of delusions. Incoherency of thought, and incompetency to manage property and person, will afford ample grounds for a commission. Where, however, as in the case of Mr. Dyce Sombre, presumed delusions constitute the gravamen of the charge that unsoundness of mind is still persisting, it becomes of immense importance to the public that the sense in which these last quoted remarks of Lord Cottenham are true in regard to delusions, should be distinctly appreciated. The following is, I believe, the doctrine of medical philosophy on this subject. A delusion may be considered as involving or implying mental unsoundness, when it is either a hallucination, *i. e.* a false perception of the senses, or a perversion of the understanding analogous to this; which latter state it is

easier to exemplify than to describe. Of the first head we have repeated instances in those who hear unreal voices and sounds, and have waking dreams of visual objects: in each case acting or reasoning off their false impressions. The wayward misconceptions of the nature and value of property, of the possession of rank, of power, and even in regard to sex, which are met with in the occupants of lunatic asylums, are instances of the second kind of delusion, supposing them similarly operative on conduct. Now with these meanings of the word delusion, in which alone the Lord Chancellor's supposition is tenable, namely, that "the existence of delusion is inconsistent with soundness of mind," we were unable to bring the delusive opinions of Mr. Dyce Sombre into any conformity or agreement. They appeared to us such, indeed, as he might have conceived, under the circumstances in which he was placed, in a healthy state of mind; and we saw no more reason for expecting that any of them should disappear with his insanity, than we might have to expect any other association, with which his mind might have been familiarised during his morbid state, to disappear at its close. For myself I should almost be inclined to doubt whether the fearful visitation of insanity had really taken place, in one on whose mind no traces of the storm were discoverable in after life in the form and texture of his associations; and this, sir, is the sense in which, I imagine, we wished to be understood, in the passage above quoted from our report, in which we speak of "those morbid impressions which do not imply unsoundness where the whole context of the character indicates sanity." Endeavouring to apply to the case before us the distinction above laid down in reference to delusions, we found no evidence that the visual mistakes of Mr. Dyce Sombre were false perceptions; and with respect to the most important of his assumed intellectual delusions, we found it impossible to place in the same category the Englishman who may fancy himself an angel, a griffin, or an emperor; and the Rajah who, happening to have formed a very low opinion of the pecuniary honesty of the East India Company, is pleased to impute to them an act of stercidity, of another kind indeed, but equally conformable with his notions of vice.

It is not my purpose to defend the opinion thus formed by us as to the imputed delusions of Mr. Dyce Sombre, but to point out that the principle on which it is formed is not, as Lord Cottenham appears to think, irreconcilable with that other principle which his Lordship affirms, that, "as long as delusion exists, there must be unsoundness, the origin of its existence,"—

provided that the term delusion is used by him in a specific sense as applicable to questions of mental unsoundness. Meanwhile, that very liability to survive the disease, which attaches to the *other* delusions of the insane because the removal of the unsoundness of mind does not imply their removal, gives additional importance to the distinction which I am endeavouring to enforce. If it be ignored, the consequences may be indefinite detention or privation of rights to any one, who having been of unsound mind, has not subsequently learnt the necessity of dissembling or concealing all such notions and opinions as may replace him in the more disagreeable entanglements of constructive insanity. Nor is this misconception confined in its detrimental consequences to the civil position of the suitor in Chancery for a superedeas. It involves in a criminal phase of the subject, much detriment and danger to the public. Thus, if the opinion entertained by Mr. Dyce Sombre in regard to the East India Company, as interfering in his family concerns, constitutes him of unsound mind and incompetent to manage his person and property, it must equally afford him the irresponsibility of mental unsoundness, if he should choose to inflict an act of violence on any one of his presumed enemies in the Honourable Board, under that singular modification of freedom which the law seems to allow him, viz. the power to do mischief. His immunities derived from his unsoundness must be commensurate with the privations which it entails on him. I may generally observe, (for I am anxious not to enter into the details of this unhappy and strangely-managed case), that the constructive imputation of insanity applicable to all persons who have been once insane, under a misconception of the nature of insane delusions, is liable to furnish an indefinite number of cases of ex-lunatics retained under some form of coercion or restriction long after their disease has subsided; and again of ex-lunatics allowed to escape the penalty of crimes committed after their enlargement or presumed recovery, on the ground that they have once been of unsound mind, and still are in possession of some of the opinions which they then entertained.

I am not aware that the leading idea which pervades this letter is at variance with the sentiments of my colleagues in the report on Mr. Dyce Sombre's case in 1849; but I ought to admit, that I have not communicated it to any one of them, and am therefore exclusively responsible.

Yours faithfully,

THOMAS MATO.

PROPOSED CHANGES IN THE APOTHECARIES' ACT—MEMORIAL TO SIR GEORGE GREY.

To the Right Honourable Sir George Grey, Bart., Her Majesty's Principal Secretary of State for the Home Department.

Apothecaries' Hall,
June 26, 1890.

SIR,—Referring to the memorial which I had the honour of laying before you on behalf of the Society of Apothecaries on the 4th ultimo, I am now desired by my colleagues to submit for your consideration the following suggestions for an amendment of the Apothecaries' Act in several particulars, in which a change in the existing law would, in the opinion of the Society, be attended with beneficial results, not only as regards the class of practitioners in this country whose education and examination the Act more immediately regulates, but also other classes of practitioners, who, not having pursued the course of study, or submitted to the examination prescribed by the Act, may still be desirous of practising as apothecaries in England or Wales.

Before proceeding, however, to state the alterations which the Society's experience leads them to suggest in the Act of 1815, I have been requested to notice one or two objections which have been urged to the Society of Apothecaries being entrusted with the superintendence of the education and examination of that class of medical practitioners.

The Society of Apothecaries, it is well known, is one of the municipal corporations of the city of London; and it is objected that it is unbecoming that the important functions which devolve upon the Society should be administered by a city guild. It is further objected that the Society of Apothecaries is a trading body, and is on that ground unfit to be entrusted with the performance of duties confessedly of a scientific character. And a further ground of objection to the Society is the name under which the holder of its certificate of qualification acquires the right of engaging in medical practice,—namely, that of the "apothecary."

As regards the first of these objections, it is to be observed that the Society of Apothecaries, which was then, as now, one of the municipal corporations of the city of London, was in the year 1815 selected by the Legislature, with the acquiescence of the Royal Colleges of Physicians and Surgeons, as a fit and proper body to be entrusted with the administration of the Act

in question, the Government having refused to constitute a fourth body for the purpose. That the selection of an existing municipal corporation for the discharge of such duties as the Act contemplated (whether wise or unwise) was certainly in accordance with established precedent, both in this country and elsewhere. The Surgeons' Company of London, which had been entrusted with duties in connexion with the science of surgery analogous to those confided to the Society of Apothecaries in connexion with the science of medicine, although separated from the Barbers in 1745 (more than a century and a quarter after the separation of the Apothecaries from the Grocers), was constituted a distinct City Company, and so continued till the beginning of the present century, when an accidental dissolution of the Company, by the sudden death of the Master on the day of election, led to the re-incorporation of the members of the old Company under the name of "The Royal College of Surgeons in London," and its connection with the Corporation of London then ceased. The Royal College of Edinburgh, also, "as the Surgeons' or Chirurgens' Craft," until within the last few days, formed one of the fourteen incorporated trades of the city of Edinburgh; and a Bill, introduced into Parliament in the present session, has just received the royal assent, one of the objects of which is to dis sever the connexion existing between the College and the incorporated trades municipal corporation of the city of Edinburgh.

With respect to the objection that the Society of Apothecaries is a trading body, much misapprehension exists. The Society in its corporate capacity is not a trading body, nor are the individual members of which the Society is composed united in the prosecution of a joint trading. No portion of the funds or property of the corporate body is embarked in trade; and no individual member of the corporation, in his character of a member of the corporation, is, or can be, benefited, directly or indirectly, by the operations which are carried on at Apothecaries' Hall. The facts are these:—Within a few years after the incorporation of the Society, certain of its members, finding great difficulty in purchasing unadulterated drugs in the market, formed a plan for supporting a Dispensary of their own at Apothecaries' Hall. This was followed in 1676 by the formation, by subscription, of a Chemical Laboratory, for the purpose of supplying the subscribers with such chemical preparations as they might require in their medical practice as apothecaries; and it appears that the supply was accordingly for some years confined to the subscribers and to the other mem-

bers of the Society. This restriction, however, was afterwards removed, and the public were permitted to purchase such preparations as they might require. In progress of time the undertaking extended itself; and at the present day the Navy, the East India Company, and numerous public institutions, derive their supply of drugs and chemical preparations from the laboratories at Apothecaries' Hall. The capital, however, with which this undertaking is carried on, is provided by a *limited* number of individual members of the Society, who are, in fact, associated together in partnership (undoubtedly under the partial control of the corporate body): but the number of such partners is considerably less than the number of the members of the Society at large; and the profits arising from the undertaking are, of course, divided among the individuals composing the partnership, and not among the members of the Society generally.

The real answer, therefore, to the objection is, that the Society is *not*, as a public body, engaged in trading operations, nor are the individual members of the Society whose capital is embarked in the undertaking I have described, traders, in the sense of men who devote their *personal* time and energies to the prosecution of a trade; but they are individuals who, being themselves engaged in the practice of the medical profession, are at the same time promoting, through the agency of competent officers, an undertaking which has for its object the production and supply of the various remedial agents of which the medical practitioner avails himself in his treatment of disease.

An objection is occasionally urged to the name of "apothecary," as designating rather a compounder of medicines than a medical practitioner qualified to treat disease. The Society have no particular partiality for the name, if a better can be found; but they feel that there are advantages in adhering to an old name, which ought not to be lightly abandoned. The functions of the English apothecary as a medical practitioner are now clearly and distinctly ascertained. Successive acts of the Legislature, followed by a course of judicial decisions, have determined his status in the medical profession, and established his legal claim to fitting remuneration for his professional services. The law forbidding the practice of an apothecary by unqualified persons, though long difficult of execution, from the cumbrous machinery by which it was put in motion, can now be expeditiously and economically enforced through the comparatively simple process of the county court; and, more than all, the apothecary of the present day (what-

ever may have been the claims to medical skill of the apothecary in earlier times) is recognised as a *well-educated medical practitioner*, thoroughly competent to the discharge of the duties which devolve upon him, and who has given satisfactory evidence of such competency before entering upon practice. There seems little temptation, therefore, to change an ancient name, which has, happily, become identified with an honourable and scientific calling.

I now proceed to state the alterations in the Act of 1815 which the Society of Apothecaries respectfully suggest for your consideration.

The Act requires that the members of the Court of Examiners should be elected from Members of the Society of not less than ten years' standing. The Society propose that in future all licentiates of the Society of ten years' standing (whether members of the Society or not) shall be eligible for seats in the Court of Examiners, and that not less than one-half of the members of the Court shall be licentiates who are *not* members of the Society.

The Society propose that power should be given to the Court of Examiners to divide the examination for their certificate into one or more examinations at proper intervals, with a view to relieve the student from the inconvenience of being subjected to an examination in all the branches of study on which he has been engaged on one and the same occasion.

At present the fee paid for a certificate of qualification for practice in London is ten guineas; and for practice in the country, six guineas. The Society propose that the fee should be equalised for the whole kingdom.

The Court of Examiners are at present required to hold their meetings at Apothecaries' Hall. The Society suggest that this restriction should be removed, and that the Court should be authorised to sit in any building which may be provided for them, not being beyond a limited distance from the General Post-office.

No person is admissible for examination, under the present act, who has not served an apprenticeship of five years to an apothecary. The Society propose that the service of an apprenticeship shall be no longer compulsory on the student.

The Society propose that there should be a registration of all persons admitted to practise as apothecaries, after examination by the Court of Examiners.

That all persons holding a degree in medicine, granted by any British University, and all members of Scotch or Irish Colleges which are authorised by law to grant a license or certificate of qualification to practise in medicine after examination,

such license or certificate conferring the right to practise medicine in those countries, should be admitted to registration, without further examination, on payment of a small registration fee.

That all surgeons, and assistant-surgeons, in the Army, Navy, and East India Company's Service, should be admitted to registration after not less than five years' actual service.

The Court of Assistants of the Society of Apothecaries, in whom the control of the Society is vested, is a self-elected body. The Society would not be indisposed to adopt any change in the mode of election of that body which might, upon due consideration, be thought advisable; but the subject has been found one of considerable difficulty. An election by the Members of the Society at large appears fraught with numerous objections, and the creation of a limited class for the purposes of the franchise has been found in practice to be productive of great dissatisfaction. The society, in truth, are not prepared at the present moment to suggest any specific change in the mode of election of their governing body; but they would be willing to give the most favourable consideration to any alteration in this respect which you might recommend for adoption.

I have the honour to be, sir,

Your most obedient humble servant,

J. B. EYLES,

Master of the Society.

MEDICAL REFORM. REPORT OF THE SOUTH-EASTERN BRANCH OF THE PROVINCIAL ASSOCIATION.

[REPORT presented by the Committee of the South-Eastern Branch of the Provincial Medical and Surgical Association, at the annual meeting at Guildford, and referred for consideration to a special general meeting of the members of the branch, held at the Town Hall, Reigate, on Wednesday, the 10th instant; at which meeting it was approved and adopted, with one dissentient only.]

The Committee of the South-Eastern Branch of the Provincial Medical and Surgical Association, in presenting their Report to their brother members assembled at this annual meeting, consider that they would be deficient in their duty did they not offer a candid and impartial statement, rendered as concise as possible, of the present state of the public affairs of the profession, more especially as affecting gentlemen engaged in general practice.

Their brother members may be assured, that at all times, and more especially at the present important crisis, the laws by which medical practitioners are governed are of superior importance to every other

consideration, as having a paramount influence, not merely on their political, but as affecting their moral and social as well as their professional welfare.

With respect to the subject of the reform of our medical polity, we might feelingly wish to say—"Would that it were settled!" but from its vital and incalculable importance, so far as the general practitioner is concerned, we cannot shrink from the consideration of it.

However much we might wish to avoid or evade it, we must all feel that in the present state of the question it affects most nearly and deeply all concerned in general practice, as well as the public at large. The obligations and duties which are attached to the subject are therefore imperative upon us.

As members of the commonwealth, as well as members of the medical profession, any system of public measures affecting the profession is as much a question of *personal duty*—as much concerns the consciences of individuals, as the determination of any doubt relating to the conduct of private life.

It has been said, and with much truth as regards individuals, "that every man makes his own place, and finds his own level in the profession and in society"—and certainly, gifted men endowed with the force of genius, talent, and industry, have, as a necessary consequence, risen to eminence under difficulties; but, in legislating for the whole profession, we are bound to conclude that the practical usefulness and elevation of character of the great majority, depend on the laws which regulate the education, preliminary and professional, of every individual candidate for medical practice.

The universal principles, therefore, of medical polity are not idle or fanciful speculations, but truths from which must be educed the educational processes which constitute the characteristics of the accomplished, able, and skilful practitioner—not merely of the favoured few, but of all who practise the divine art of healing, whether exercising it in our great metropolis or large provincial towns, or in remote and thinly-peopled districts.

After many and often-repeated applications, and solicitations almost humiliating, from the various representatives of the general practitioners, the Council of the College of Surgeons have rejected all propositions, and have repudiated the deliberate and solemn engagements of their delegates, to the great disappointment of the other parties to the conference committee at the College of Physicians.

After these anxious and hopeless endeavours, therefore, the general practitioners must come to the conclusion of the utter impossibility of rendering the College of

Surgeons what has been appropriately and emphatically termed their "head and home."

The Society of Apothecaries have deserved well of the profession and of their country, from the able and efficient manner in which they have carried out the provisions of the Act of 1815. Nothing could surpass the caution, judgment, and ability with which their Court of Examiners have gradually raised their scale of required attainment in candidates for their certificate of qualification, and for which we are infinitely indebted to them.

Your committee therefore trust that they will firmly adhere to the determination which they have expressed, namely, never to resign their powers under that Act until an incorporation of the general practitioners can be effected, which, as able and enlightened men, they judge to be equal to their wishes and expectations, and all-sufficient to render the future general practitioners fully competent to meet and treat successfully all the extraordinary, as well as ordinary, emergencies of medical and surgical practice.

Under all the circumstances of the present state of the case, your committee do not hesitate to recommend, as of pre-eminent importance and desirableness, the incorporation of the general practitioners in an independent College, which, to the credit of the Council of "The National Institute of Practitioners in Medicine, Surgery, and Midwifery," has been advocated by them with the greatest truth and clearness of argument, a steady perseverance, a calm dignity, and an incomparable temper, for a long course of time, and under many circumstances of difficulty and discouragement, so as richly to deserve the warm approbation of the whole body of general practitioners.

With the same steady and unflinching courage these gentlemen will persevere until the accomplishment of a separate college is complete; but at the same time they call upon the general practitioners at large to afford them their cordial support in their meritorious exertions, and throughout the country to co-operate, and, with united action, to interest their influential and parliamentary friends in favour of a new and independent college, assured as they must be that it is the only practicable organization by which their interests, and the interest of the whole population of the country, as respects their health, can be secured.

Your committee, therefore, have no hesitation in submitting for adoption at this meeting the following propositions, as unquestionable, as well as important truths.

1. That medicine, surgery, and midwifery, are departments of the same profession, which are inseparable in an educational and

scientific point of view; and in the exercise of the profession, they are equally inseparable for nine-tenths of the practitioners of the healing art.

2. That the practitioners of the three branches of the profession are the medical advisers, in ordinary, of almost the whole population of the country, whose health, comfort, and well-being depend on the competency and skill of those to whom they look up for counsel and assistance under the various forms of disease which occur.

3. That every defect in the medical institutions of the country, or any line of policy calculated to retard the progressive improvement of the general practitioners, or to depress the standard of their qualification, or to diminish their scientific and practical attainments, or in any way to lower their status in society, will have the effect of debasing the character of the profession in this country, and is fraught with incalculable direct and consecutive evils to society at large.

4. That in consequence of the failure of negotiations which have been going on for a great length of time, and the occurrence of recent events, your committee entirely despair of being able to obtain any alteration or modification of either of the existing Colleges, so as to acquire the means of securing a complete and scientific medical and surgical education for the general practitioner, and entertain the strongest conviction that the objects of medical reform, so far as respects him, can now be certainly attained only by the establishment of a new College on the representative principle, distinct and different from either of the existing institutions, which shall provide for the education, qualification, and examination of all its future members.

5. That the accomplishment of such a measure would develop the energies of the medical profession to an extent hitherto unprecedented, and would sustain the usefulness and respectability of its practitioners, in not only promoting the science and art of medicine and surgery, but also, as bearing on public health and sanitary improvement, would be one of the most direct and efficient modes of ameliorating and preventing many physical and social evils which are found to prevail both in town and country.

The establishment, therefore, of a new College of general practitioners on the representative principle, by royal charter, confirmed by Act of Parliament, providing an efficient control over the education of members of that class, so that their progressive improvement in preliminary knowledge, in the collateral as well as medical sciences, tested by sufficient examination

would secure the true respectability and usefulness of the great body of practitioners, to whose skill and judgment the limbs and lives of the great mass of the population are confided.

It is with much reluctance your committee desire to recall the attention of the meeting to several recent leading articles in your journal. The gentlemen who have in other respects so ably conducted the general management of that periodical have, it appears to your committee, not written their leaders, referring to the question of medical reform, with that candour and fairness which the numerous members of the Association who differ from them had a right to expect. The result of the opinion of the special branch meetings may warrant the conclusions they come to; yet those opinions, which have been gathered under peculiar circumstances, might have been promulgated in a way less likely to disturb that harmony which it is the object of the association to maintain.

There are three prevalent fallacies which, *a priori*, are so obviously improbable, that your committee would not have thought of advertizing to them, but that they appear to exist in the minds of some general practitioners.

One is, that in the event of the establishment of a new College, they would lose, or be obliged to lose or relinquish, the title of "surgeon," which, in the first instance, is manifestly unlikely, and is actually untrue.

The second is, that we entertain a desire to supersede the College of Surgeons, which would not be possible, did we wish it ever so much.

We all acknowledge the advantage of consulting surgeons, as well as consulting physicians, and with perfect friendliness and cordiality of good feeling do we view the existence and the prosperity of that as a special College.

May it long enjoy a prosperous career, directed by liberal and generous principles—a high degree of public virtue—an enlightened, and not a low and gross selfishness!

And may its diploma be the reward of merit, and be justly appreciated as being rather difficult, instead of continuing to be too easy of attainment!

The third is, the fear of a supposed inferiority of the new College. Whereas, a College comprehending the practitioners of all the three branches of the profession, all the sections of the healing art, with high qualifications in every department, must, surely, be as dignified and as elevated in its attributes as any College taking into its study and qualification of membership one section only, and a supposed practical

exercise of one division only, of the profession.

With respect to the benevolent fund of the Association, its able and indefatigable advocate will not fail to be present on this occasion.

Your committee, therefore, will be content with recommending it to your kind consideration, and of again submitting the often-repeated suggestion, that the small annual contribution of five shillings from each member would form, altogether, a handsome income.

With regard to the subject of poor-law medical relief, your committee regret that they cannot announce any progress; and in this matter, perhaps, more than in any other, is the want of a real and effective representation of the wants of the medical profession most keenly felt.

Grievances of a pressing nature, acknowledged by every one who has investigated the subject, weigh upon a large portion, numerically, of medical practitioners; and, although the constituted authorities of the profession express sympathy with their suffering members, no authoritative or energetic remonstrance is offered by them to those branches of government with whom the redress of these grievances should be a matter of duty.

Could such a state of things endure if the interests of the profession were in the hands of an energetic body, sincerely anxious for the good of the great mass of their constituents?

Your Committee have no hesitation in stating that, in their opinion, active and repeated efforts should have been made by the Colleges of Physicians and Surgeons to obtain for the three thousand poor-law medical officers that justice which is so notoriously denied to them.

And your Committee as fully believe that such efforts would have been crowned with success.

In the absence of an authoritative adoption of their cause by the recognised heads of the profession, the poor-law medical officers have remained disunited—their efforts feeble—their success null; and this great opprobrium to a rich, and considering itself an enlightened country, as well as to a profession daily claiming more and more of a scientific character, remains undiminished, with some of its evils even aggravated.

For the convenience of gentlemen residing in different parts of the district, it has been usual to hold the annual meetings in a sort of order of succession, which will give the preference next year to East Kent.

The town of Folkestone, by the convenience of its railway communication, and as being the birth-place of Harvey, your

Committee consider to be an appropriate place of meeting for next year, and beg to recommend it to the adoption of the members present for the assemblage of 1851.

JAMES STEDMAN,
Chairman of the Committee.
THOMAS MARTIN,
Secretary.

COPY OF A RESOLUTION adopted, with one dissentient only, at a special general meeting of the South-Eastern Branch of the Provincial Medical and Surgical Association, assembled at Reigate on the 10th instant:—

“Moved by Mr. Smith, of Crawley, seconded by Mr. Dulvey, of Brompton, Chatham, and

“Resolved—That the report which has been adopted be inscribed in the minutes, and printed for circulation, as has been usual on former annual occasions.

“And that the editors of the medical journals be respectfully requested to favour this meeting with the insertion of the Report in their next number.”

Reigate, 11th July, 1850.

PROPERTIES OF THE WATER OBTAINED FROM WENHAM LAKE AND NORWEGIAN ICE—A SUBSTITUTE FOR DISTILLED WATER.

IN confirmation of the observations of Mr. Faraday on the purity of water obtained from Wenham Lake and Norwegian ice,* a specimen was lately submitted to examination, with the following results:—The water was colourless, tasteless, and rapid; it was free from acid and alkaline reaction; was not affected or rendered turbid by nitrate of baryta, oxalate of ammonia, nitrate of silver, ammonia with phosphate of ammonia, or lime water. It gave only a slight opacity after some minutes with acetate of lead, but this was no greater than the effect produced by the same reagent on distilled water.

Tried with the soap test, it marked 0° of hardness; and, when a sheet of polished lead was plunged into it, a white deposit of hydrated oxide and carbonate of lead was formed in an hour. These facts show that the water derived from pure ice is absolutely pure, and may be used in remote places as a substitute for distilled water when this cannot be readily procured. This suggestion may be of use to those who have hitherto found a difficulty in procuring an abundant supply of distilled water for the purposes of chemical research.

The rapid action on lead is in conformity to general experience, and is a strong indication of the great purity of ice-water. The

fact that white lead is so abundantly produced by the contact of this metal with ice-water may be of some importance in relation to health, since it would render it unsafe to employ refrigerators lined with lead for the purpose of preserving the Wenham Lake or Norwegian ice.

It should be observed that the water here experimented on was derived from ice absolutely transparent and pure, without air-bubbles. Some kinds, when melted, produce a kind of water which has a slight opacity, obviously from the presence of impurity.

CONFESSION OF PROFESSOR WEBSTER.

LETTERS from the United States announce that Professor Webster has confessed the murder of Dr. Parkman. He states that the deceased went to his (the professor's) room on the fatal day to receive some money owing to him by the prisoner; that he provoked him without measure by taunting reproaches and threats, thrust his fist in his face, and called him liar, scoundrel, &c., and that in the heat of passion thus roused he (prisoner) dealt a sudden blow at the deceased, which almost immediately destroyed his life. His confession, which is very long, adds, that the thought of proclaiming the deed, and explaining the circumstances, never entered his head, but that he at once determined on concealment, and took measures for that purpose with singular composure and skill. He confesses to having afterwards cut up the body, and, having burnt several parts, thrust the trunk into a sink. The confession seems to be pretty generally believed, but it is thought that it would have been of more avail to him if it had been made immediately after the event. He solemnly declares that he never for a moment premeditated the murder, and asserts that his temper has been always uncontrollable.

* * We have hitherto delayed giving a report of this remarkable trial, owing to the crowded state of our columns. We shall, however, take an early opportunity of publishing the evidence in an abbreviated form.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 11th July, 1850:—Edward Simpson, York—John Todd, Rothbury, Northumberland—William Charles Hille, London—Henry Noble Watson, Clitheroe, Lancashire.

EPILEPSY FROM PRESSURE UPON THE BRAIN.
(CLINIC OF JEFFERSON MEDICAL COL-
LEGE.) REPORTED BY MR. JAMES A.
MEIGS, STUDENT OF MEDICINE.

A CASE of considerable importance in surgery was presented by Professor Pancoast to the class of Jefferson Medical College, on Saturday, January 13th, 1849.

The patient, a lad aged 14 years, had, about nine years previous, received a severe blow upon the sinciput, just over the left orbital ridge, by being precipitated from a cart upon a pile of stones. He was taken up insensible; but, under judicious treatment, recovered, and was to all appearance perfectly well. Some time after, when the circumstance was almost forgotten, the patient was suddenly seized with epileptic fits, a disease with which, prior to the accident, he had never been troubled. These untoward symptoms gradually increased in frequency and violence, until it was not uncommon for them to recur ten and even twenty times per diem.

Coincidentally with this epileptiform condition, a slow but progressive decay of his mental faculties became evident, till it was finally feared a total alienation of his mind might supervene. As indicative of this, his features were impressed with the peculiar fatuous expression of confirmed epileptics, while his whole conduct evinced a moody and abstracted state of mind.

These abnormal symptoms had thus far been steadily increasing in magnitude and violence, despite the various and well-directed remedies employed, when the patient was placed under the charge of Professor Pancoast, who, after a careful investigation, both of the history of the case and the condition of the lad, became convinced that the evil resulted from the pressure of a portion of the vitreous table of the os frontis upon the anterior lobe of the left cerebral hemisphere. This projection of the bone he thought had been undoubtedly established at the time the accident occurred, but had not manifested itself by its alarming results,—the child being then very young,—until the brain became considerably developed.

Here, then, was an extremely delicate point for the formation of a diagnosis, and the establishment of the consequent treatment. The question forcibly presented itself, whether to operate or not. If the meninges of the brain were inflamed, or the orbital plate broken, it was obvious that no benefit would accrue, and the patient be needlessly subjected to a painful operation.

Again, if the frontal sinuses existed to any extent, the danger was manifest of forming cranial fistula, which would be extremely difficult, if not impossible, to cure.

Notwithstanding these manifold obstacles, the operation was resolved upon, inasmuch as it seemed to give the lad the only chance for his recovery.

His father assenting, the lad was brought before the class on the 17th of January. He was placed upon a table in the clinical room, and as a return of his paroxysms during the operation was feared, he was held firmly down by several assistants. A sort of triangular opening was made, the flaps of which being turned back, the pericranium was exposed. This was divided, and the branches of the supra-orbital and frontal arteries, the hemorrhage from which was considerable, were taken up. The trephine was now applied immediately above the superciliary ridge, and as near the depression as possible. Extreme caution was necessary at this point of the operation, this being a difficult and dangerous place for the application of the trephine. In this case the danger was increased by the incessant struggling and resistance on the part of the patient. A circular piece of the skull was removed, having upon its inner face a spiculum of bone pressing upon the dura mater; thus triumphantly verifying the diagnosis. The dura mater was perfectly healthy, presenting its usual opaque pearly hue.

The edges of the periosteum being brought together, and the flaps laid down and supported by a compress of wetted lint, lightly held in its place by adhesive strips, the patient was transferred to one of the clinical wards of the institution. Here he remained during the ensuing month, under the attendance of Drs. Rand and Horner.

For some time after the operation, it was frequently noticed as a fact worthy of consideration, that any attempts to approximate the lips of the aperture closely, and thereby dispose them to heal at once, were speedily followed by a return of the epileptic paroxysms, which were as readily dissipated by the immediate removal of the approximating force. The same disagreeable results were also found to be induced by the slightest indulgence in any highly nutritious or stimulating aliment.

In addition, therefore, to cold applications to the head, absence of light, and the scrupulous avoidance of all anodyne preparations, which were resorted to immediately after the operation, the lad was kept upon a spare diet, and the aperture allowed to remain open for nearly a month. The judicious nature of this treatment was soon made manifest by the happy restoration of the lad to mental and physical health.

The scar necessarily left by the operation is scarcely perceptible, while the aperture is filled up with a cartilaginous deposit, as is evident from the resistance offered upon pressure.

The lad is now (August 1849) employed by his mother to run errands, and attend occasionally to a little store which she keeps in this city. In his daily conduct he evinces an intelligence and physical strength usual to lads of his age and condition in life.—*Phil. Med. Examiner.*

PATHOLOGICAL ANATOMY OF CHOLERA.

MICROSCOPIC examination has shown, as being constantly present in this disease, an abnormal state of the intestinal follicles, with or without enlargement, and a more or less vivid injection of Peyer's glands. At the hospital of Val de Grâce, besides these morbid changes, there were found, in the young soldiers who have died of algide cholera, ecchymoses in the parenchyma of the liver, spleen, kidneys, and lungs. These ecchymoses appeared not only on the surface, but also in the interior, and seemed to result from a combination of the blood with the tissue of the organs. In the large intestines, these ecchymoses have been found so extensive and deeply coloured, as to resemble gangrenous patches.—*L'Union Médicale.*

WOUND OF THE BRAIN—RECOVERY. BY WILLIAM KENNEY, M.D.

THE subject of this case was a lad 17 years of age, who received a stab with a common pocket-knife, blade two inches and a half in length, and three-quarters of an inch in width, tapering abruptly on back and edge to a point. The wound was in the left temporal region. The knife was driven with such force as to penetrate the brain the full length of the blade, at a point midway and about three-quarters of an inch above a line drawn from the external angle of the eye to the *meatus auditorius internus*. The handle of the knife, as it stood, looked slightly forwards and upwards, and was so firmly fixed between the divided bone that it was with great difficulty that the knife was removed. During its presence in the brain, and after its removal, the patient complained of great pain in the left eye, and over the frontal region of that side. Its removal was followed by hemorrhage, to the amount of ten or twelve ounces; vomiting and stupor. The patient was taken from the street, his wound washed, and without farther dressings being applied, he was placed in bed, with the head raised, and ordered the free use of cold applications to the scalp; sinapisms to the extremities; twenty grs. calomel; rest and quiet. Under this treatment, in less than three weeks he entirely recovered.—*American Journal of Med. Sciences*, Jan. 1850.

BOOKS & PERIODICALS RECEIVED FOR REVIEW.

(The List will be given in our next No.)

BIRTHS & DEATHS IN THE METROPOLIS During the Week ending Saturday, July 13.

BIRTHS.		DEATHS.	
Males....	608	Males....	305
Females..	637	Females..	386
	1245		781

CAUSES OF DEATH.

ALL CAUSES	781
SPECIFIED CAUSES	760
1. <i>Zymotic</i> (or Epidemic, Endemic, Contagious) Diseases....	166
<i>Sporadic Diseases</i> , viz.—	
1. Dropsy, Cancer, &c.	36
2. Brain, Spinal Marrow, Nerves, and Senses	104
4. Heart and Bloodvessels	21
5. Lungs and organs of Respiration	57
6. Stomach, Liver, &c.	50
7. Diseases of the Kidneys, &c.	11
8. Childbirth, Diseases of Uterus, &c.	11
9. Rheumatism, Diseases of Bones, Joints, &c.	8
10. Skin	1
11. Old Age	35
12. Sudden Deaths	7
13. Violence, Privation, Cold, &c.	12

The following is a selection of the numbers of Deaths from the most important special causes:

Small-pox	9	Convulsions	27
Measles	16	Bronchitis	20
Scarlatina	23	Pneumonia	42
Whooping-cough	23	Phthisis	116
Diarrhoea	37	Lungs	4
Cholera	7	Teething	11
Typhus	30	Stomach	6
Dropsy	7	Liver	16
Hydrocephalus	26	Childbirth	5
Apoplexy	29	Uterus	5
Paralysis	18		

REMARKS.—The total number of deaths was 105 below the average mortality of the 26th week of ten previous years. The only point worthy of remark is, that there were seven deaths from Cholera. The disease, however, was the common English epidemic, and not the malignant form.

METEOROLOGICAL SUMMARY.

Mean Height of the Barometer 29.77

 Self-registering do. " Max. 110° Min. 34°
 " From 13 observations daily. " Sun.

RAIN, in inches, 0.52.—Sum of the daily observations taken at 9 o'clock.

METEOROLOGICAL.—The mean temperature of the week was 1°.5 below the mean of the month.

NOTICES TO CORRESPONDENTS.

Description of a new Method of converting Gas, &c. into Fuel for Fire: with some Observations on its bearing upon the Sanitary Condition of Towns, by D. O. Edwards, Esq. M.R.C.S. has been received.

The letter of Mr. B. W. Richardson shall appear next week.

The long document on Self-supporting Dispensaries can only be inserted as an advertisement. Communications have been received from Dr. Hassall, Mr. Girdlestone, and Mr. Galloway (No. 2).

Lectures.

LECTURES
ON THE
TREATMENT OF DELIRIUM AND
COMA;

(IN SEQUEL TO THE LUMLEIAN LECTURES
FOR 1850.)

Delivered at King's College Hospital,

By R. B. TODD, M.D., F.R.S.

(Reported by Mr. LIONEL S. BEALE, Med. As-
sociate K.C.L.)

LECTURE VI.

Hysterical delirium in men.—Treatment of epileptic delirium—Diagnosis of epileptic delirium—Epileptic delirium a prolonged epileptic paroxysm—can it be cut short? Bleeding—Moral treatment—Treatment of coma—Diagnosis of apoplectic coma.—Treatment of traumatic coma, of epileptic coma, and of the other varieties of coma.

GENTLEMEN,—In my last lecture I directed your attention to a case of hysterical delirium, now in King's College Ward; I refer to this case now, in order that I may tell you that this patient is going on very favourably under the plan of treatment which we have adopted; namely, paying due attention to supporting her strength with nutritious diet, and isolating her from other patients in the ward by placing screens round her bed, at the same time exercising a firm but mild moral influence upon her, without mechanical restraint.

I must here allude briefly to the treatment of that form of delirium which we now and then meet with as apt to occur in men who have been very hard-worked: over-worked, either as students, or in their professions or other callings, or who have drawn too largely on their powers by habits of dissipation, especially when sexual excesses have been conjoined with them. In such persons, I say, we now and then meet with a form of delirium which often passes under the name of brain-fever; this delirium is closely akin to that of hysteria in women; indeed, the state into which men bring themselves by overtaxing their powers is very similar to, if not identical with, the hysterical state in women, and the delirium which is developed in the course of it is therefore most probably of precisely the same nature.

The occurrence of a delirium of this kind in men forms an interesting feature in reference to the pathology of hysterical affections, inasmuch as it clearly shows that the hysterical is not a condition especially connected with the peculiar characters of the female sex, but that, under circumstances

analogous to those which are apt to produce it in women, a similar state may be brought on in men.

Men who addict themselves to masturbation, or to excessive sexual indulgence, become affected with nervous symptoms precisely of the same nature as those which are so common with hysterical women. They become effeminate in appearance and habits; and often, if I may so speak, more effeminate even than women. In such men you may witness the hysterical paroxysm as complete and as intense as any that may be seen with women. Men of strong sexual passions, even although they may be kept under proper restraint, when exhausted by other means, as by undue mental exertions or anxiety, likewise become hysterical, although to a less extent than when the exhausting cause has been sexual.

The hysterical states, then, in both men and women, may be regarded as pathologically the same. The very same rules of treatment which I have laid down for the management of the hysterical delirium of women are applicable to that of the hysterical delirium of men; namely, careful attention to the support of the patient's general nutrition and to the state of his digestive organs, moral management, isolation as far as may appear advisable according to the particular circumstances of the case, which also, rather than any general rules, must guide you as to the use of sedatives, tonics, and stimulants.

Treatment of epileptic delirium.—I have not yet had an opportunity of speaking of the treatment of that most interesting form of delirium which I have ventured to designate *epileptic delirium*. It is met with in persons subject to epileptic fits, or it may occur in persons who have never had a fit, but who are disposed to epilepsy, and may have the complete epileptic paroxysm at some future time. Epileptic delirium may come on before or after a fit; it usually comes without any forewarning, and having lasted a certain time, passes off,—why, we cannot tell. Many of the cases which are designated *acute mania* are most probably of this kind. In many such cases epilepsy may be found to have affected some members of the patient's family. So also the cases of the so-called *phrenitis* are examples of epileptic delirium. Now it is obviously of great importance to be able to diagnose a case of epileptic delirium, and to draw a clear distinction between it and the several forms of delirium which I have described.

For the purpose of this diagnosis you must avail yourselves of both negative and positive evidence. By the former you will be able to exclude the various other forms

of delirium which I have enumerated. The history, and the absence of certain obvious phenomena, will denote that it is neither erysipalatos nor typhoid, nor pneumonic nor rheumatic; and the absence of certain other symptoms, as pain in the head, sickness, sluggish pulse, and the non-existence of the tendency to coma, will point out that the symptoms are not due to inflammation of the brain or its membranes. Then you must satisfy yourselves that it is not delirium tremens; in which you will again derive much aid from the history of the patient, and from ascertaining whether he has been intemperate in his habits or not; also from the absence or presence of the peculiar tremor in the voluntary actions, and from the character of the delirium, which in delirium tremens is generally of the busy kind. You will further inquire whether the patient's delirium may not be of the hysterical kind, to which I referred in a former lecture; whether he had not subjected himself to exhausting influences, sexual or otherwise, and so given rise to the delirious state.

Having thus determined that the delirium under which your patient labours is not to be referred to any one of these varieties, it is highly probable that it must be of the epileptic kind; and you must now look for some positive signs to prove that it is so. The aspect of the patient will afford some help: there is, in these cases, a peculiar haggard, wearied aspect of the countenance, with dilated pupils, which should always excite your suspicions as to the epileptic nature of the disease. The character of the delirium is also to be taken into account; it is almost always of the noisy and violent kind; the patient is uproarious, to use a common expression, wakeful and talkative. Then, if previously the patient have suffered from regular epileptic paroxysms; if the delirium have been ushered in with a fit; if epilepsy be distinctly a feature of his family history; if the convulsive fit have occurred in the course of the paroxysm of delirium,—any or all of these points will assist you greatly in determining the epileptic character of the delirium.

What, then, is the appropriate treatment for a case of epileptic delirium? Have we any royal road to cut short the paroxysm, and bring the patient quickly to his senses? I fear that we can no more cut short this maniacal paroxysm, than we can cut short the convulsive fit of epilepsy.

Indeed, the paroxysm of delirium may be looked upon as a prolonged epileptic fit. It is a fit in which the disturbance of cerebral nutrition is mainly limited to the convulsions of the brain. In the ordinary convulsive fit, the parts of the brain which are affected are probably the tubercula quadrigemina and the hemispheres: in the de-

lirious fit, *without convulsions*, the latter parts alone are affected. In some of the milder cases of epileptic disease we see this isolation of the mental affection and of the convulsive very conspicuously. Thus, we observe in some cases that the paroxysm consists only in a momentary loss of consciousness, from which the patient instantaneously recovers; while in others it consists of sudden convulsive starts affecting the upper or lower extremities or both, and which, when the latter are affected, are sometimes so severe as to throw the patient down. Yet in many of these the patient retains his consciousness perfectly undisturbed. You have examples of both of these states now in the hospital; one in Sutherland ward, in the man whose skin was darkened by a course of nitrate of silver, which he took before his admission. This man has the smaller fits of loss of consciousness, momentary faintings, of which he will sometimes have several in the course of the day. The other case is a lad of Jewish parents, who has the convulsive startings to a very great extent, sometimes fifteen or twenty times a day, and frequently with great violence; but he assures us that never, in even the most severe of them, by which he is thrown down with violence, does he lose his consciousness. This lad, however, has also the regular and fully developed fits, but not more frequently than once in three or four weeks.

It is not, then, unreasonable to suppose that if you may have a short and very temporary affection of the intellect and consciousness, you may also have a prolonged affection of them, constituting the epileptic delirium, which may be ushered in by a regular fit, or which may be determined by a regular fit.

Now I apprehend that no one, now-a-days, will pretend that we have as yet discovered any mode of cutting short the ordinary epileptic convulsive paroxysm. Many means for this purpose have been proposed; such as putting salt in the mouth, pressure on the carotids, bleeding, splashing with cold water, but none have been followed with any degree of success which justifies us in adopting them. I do not say that you may not, if you fancy, try the more harmless of them, such as the salt, and the cold water; but anything which interferes with the circulation is dangerous, and must not be tried on light grounds.

I do not believe, then, (to answer the question which I just now proposed), that we have any sovereign means of cutting short the paroxysm of epileptic delirium; and, therefore, I regret to say, that very much of the advice I have to give you on the management of these cases must consist of cautions to you as to what you ought not to do, rather than of positive instructions as to what you must do.

We have, in fact, in the treatment of a case of this kind, to guide our patient through a prolonged epileptic fit; to support his powers until the excitement of the paroxysm passes off, and to guard him against injury. Time is the great element in his cure, and the clinical history of similar cases gives us the best assurance that the paroxysm will in time, if we do not allow the patient's strength to be exhausted, exhaust itself. Our treatment, then, must be mainly *supporting* and *expectant*, with due attention to the ordinary functions of the digestive organs.

And now I must tell you what you ought not to do.

In the first place, as we have the most satisfactory evidence that there is no inflammation of the brain in these cases, you need not harass your patient by the employment of antiphlogistic remedies. You must not bleed him: there is no necessity nor demand for this practice: it often increases the violence and the duration of the ordinary epileptic paroxysm, and it also tends to increase and prolong the delirium, as it does in other forms of delirium. Neither is it advisable to bleed locally, either by leeches or cupping,—or, if you think it prudent to yield to the solicitations of friends, take care to be very sparing in the quantity of blood you take away. When the pulse is strong and slow stimulants are not required; your patient will be better without them: but when the pulse is weak, vacillating, irregular, and more especially when it is quick and running, then stimulants carefully given will prove advantageous. You may shave the head; and, if it be hot, apply cold applications, but in such a way as not to depress the heart's action. This will give the patient and his attendants something to do, and enable you to proceed the more comfortably with your expectant plan.

You may likewise apply small blisters in succession to the scalp, but do so without irritating the patient much, and desist immediately if it seem to have that effect. The moral treatment is particularly to be noticed here, as in many cases it proves of great benefit: all causes of excitement should be carefully avoided. As to restraint, you must exercise the rules I mentioned in speaking of delirium tremens. All means must be taken to prevent the patient from injuring himself; but the gentler the means employed (provided they be effectual) the better. Upon this point I should be glad, if I had time, to read to you some extracts from Dr. Comolly's valuable lectures on the treatment of acute mania, published in the *Lancet*; but I advise you to peruse them for yourselves—to read, mark, learn, and inwardly

digest the wise and humane cautions there given as to the management of these cases.

Sometimes there is extreme wakefulness, and you cannot get the patient to sleep. What are you to do? Avoid opium, generally speaking: if you give a sedative at all, let it be hyoscyamus or hop. Sometimes the cold douche or the shower-bath prove very effectual in inducing sleep. The head may be placed out of bed, and cold water poured upon it from a height, or it may be very freely sluiced with a large sponge. I have seen chloroform of great use where opium had utterly failed: but you must bear in mind the same precautions with regard to its use as to the use of opium; do not give it if you can do without it. Any other drugs which you administer should be of the tonic kind, of which the most useful are the metallic tonics, as zinc and iron, or you may give bark or quinine.

Of the treatment of coma.—The advanced period of the session warns me that I must bring these lectures to a close. But I have yet to speak of the treatment of the different kinds of coma. Fortunately, it will not be necessary for me to occupy your time at much length with this subject. I have in the course of these lectures adduced the strongest evidence that, in the great majority of instances, the state of coma is but a more advanced stage of the same essential condition as the state of delirium. Therefore, much of what I have said of the treatment of the various forms of delirium will apply to that of the corresponding forms of coma.

Now, in speaking of the general treatment of coma, I must exclude the apoplectic coma; by which term I mean coma produced by extravasation of blood, or by pressure of some other kind upon the brain,—as from fracture of the skull with depression of a portion of bone. I must likewise exclude that comatose state which arises from inflammation of the brain.

In dealing, then, with any particular case of coma, you must assure yourselves, in the first instance, that it is not coma from pressure, and that it is not coma from inflammation of the brain. I need not dwell here upon the symptoms of inflammation of the brain, as I have already sufficiently discussed that subject in a former lecture; but I shall make a few remarks as to the diagnosis of the coma which is brought on by effusion of blood within the cranium.

This diagnosis is by no means always easy: with the greatest precautions, you will now and then find yourselves mistaken,—so closely do the symptoms of one

kind of coma often resemble those of another.

The points to which you must look are—

1st. The history of the case.

2d. The mode of accession of the coma.

3d. The state of the pupils.

4th. The existence of a paralytic state.

In most cases of apoplectic coma there have generally been some threatnings beforehand; such as pain or uneasiness in the head, giddiness, *muscæ volitantes*, tinnitus aurium, or other subjective phenomena of the senses. You will be particular to inquire about these points. The coma of apoplectic effusions always comes on more or less suddenly. The sudden supervention of coma in a man previously healthy affords a strong presumption in favour of the apoplectic nature of the coma; and this is especially the case when there have been no convulsions, no mental excitement or emotion, previous to the attack, and when epilepsy does not appear in his history. A dilated state of the pupils generally accompanies the apoplectic coma; but as this is very common, even to a greater extent, in epileptic coma, it gives us no efficient aid in the diagnosis. When, however, one pupil is dilated, and the other natural or contracted, we may have strong suspicions of injury of the brain. This is especially the case if the coma be accompanied or preceded by paralysis of one side of the body.

When the apoplectic effusion takes place in the vicinity of the third pair of nerves, tearing up the brain more or less, a highly contracted state of the pupils is apt to take place.

The sudden occurrence of a hemiplegic paralysis simultaneously with the state of coma affords a strong indication that the cause is an apoplectic effusion. Even with this symptom, however, you will occasionally be deceived. In the Lumleian Lectures I referred to a case of this kind, in which there were sudden hemiplegia and profound coma, and after death I was unable to find a clot in the brain.

In investigating cases of coma you must be most careful to inquire into the state of the renal and hepatic secretions. When either the liver or the kidneys fail, the patient becomes comatose. The liver may fail either from actual non-elimination,—the elements of the bile remaining in the blood,—the liver having lost its power of attracting them out of it,—or there may be some mechanical impediment to the flow of the bile, either in disease of the ducts themselves within the liver, or in some stoppage of the hepatic or common ducts outside the liver. The hepatic derangement shows itself plainly enough in the jaundiced state of the patient. When the kidney is

at fault I need not tell you that you will find the evidence of it in a careful chemical microscopical investigation of the urine.

The former history of the patient affords the most valuable and important guidance in the diagnosis of the various forms of comatose affections. You must inquire into the state of the patient previous to the occurrence of the coma, and must consider whether he has been the subject of epilepsy, gout, rheumatism, hysteria, or renal disease, as the coma may arise from any of these conditions. You should also inquire into the previous habits of your patient, as to intemperance, taking opium, &c., as coma may arise from the presence of opium or of alcohol in the system.

You must, then, before you fix upon your line of treatment, be satisfied that the coma is not apoplectic,—that is, from pressure; and also that it is not due to the presence of opium or of alcohol in the system.

Excluding these, the coma may be traumatic, from shock, producing simple concussion of the brain, or it may be epileptic, or renal epileptic, or hysterical, or rheumatic, or gouty. I shall not dwell upon the diagnosis of these forms of coma from each other, but proceed to refer briefly to the treatment of each.

First, then, as to the *traumatic coma*. This is that state which surgeons describe under the name of concussion of the brain. We have unquestionable evidence that it is not a state of inflammation, or of active disease of any kind, but simply one of suspension of the powers of the brain due to the shock occasioned by the injury. We do not know exactly what the precise condition of brain is in this traumatic coma. It is, however, a state analogous to that of sleep, in which the natural actions of the brain are depressed rather than exalted: to use an expression borrowed from the Stock Exchange, they are *below par*. In the milder cases, as when a patient is simply *stunned*, recovery takes place quickly and perfectly without any medical interference. Why should not this be the case with the more prolonged cases, in which the stunning effects of the injury last considerably longer? Indeed, I do not know why it should not; and I believe that in the great majority of cases this state of coma passes off spontaneously, just as it does in the slighter cases.

Are we, then, in cases of concussion of the brain, to content ourselves with looking on, and to do nothing? I believe that the opinion is rapidly gaining ground that this expectant method,—this system of non-interference,—is the best. Upon this point, however, I speak with diffidence, and must refer you to the great surgical authorities.

I shall only add, that most of those with whom I have conversed on this subject have expressed themselves most favourable to this plan. Among them I may especially refer to my friend and neighbour Mr. Bransby Cooper, whose large experience at Guy's Hospital entitles his opinion to great weight. In conversation upon this subject, he likened the state of coma after concussion to a state of sleep which has a distinctly reparative object and effect.

Most of you will remember the case of a woman who was thrown from a window by her husband, not long ago admitted into one of the surgical wards. This woman had very decided traumatic coma. At first it was thought that some depression of bone had taken place; but it was soon found that the injury was limited to the external table of the skull. This patient recovered completely and most satisfactorily under a treatment which was mainly of the expectant kind.

Then do I advise you absolutely to do nothing in these cases? My advice is, to attend to the functions,—relieve the bowels by mild means, support the system without stimulating the patient, unless great debility calls for more active support; and, that you may not appear to the friends of the patient to be absolutely inactive, shave the head, apply cold to it, or, if there be no contra-indication, apply a small blister now and then.

Formerly all these patients used to be bled, almost as a matter of course, and with the view of anticipating the inflammation which it was expected would follow upon reaction after the shock. But this idea of inflammation following reaction rests upon no good ground: it was suggested by the occasional occurrence of delirium after this form of coma, the delirium being supposed to indicate a state of inflammation. We now, know, however, that delirium is by no means a certain indication of inflammation within the cranium, and more especially delirium arising out of coma. Delirium *passing into* coma would be a more likely indication of an inflammatory affection.

You will ask, are there no circumstances which justify bleeding in cases of traumatic delirium? I cannot take upon myself to answer this question in the negative. I do, however, say that it appears to me a very unmeaning practice to bleed in anticipation of inflammation; and that you should wait for some decided symptom, some good evidence of inflammation or of congestion, before you subject your patient to the risks which arise out of the loss of blood.

Treatment of epileptic coma.—The epileptic coma is the most common form of coma we meet with; and here, like-

wise, the expectant mode of treatment, with moderate purging, answers better than any other. This condition presents many analogies to the traumatic coma. The brain experiences a shock from the epileptic discharge. The shock is generally followed by a longer or shorter sleep, from which the patient awakes up relieved, and often with no other symptom than a feeling of exhaustion. We do not find that anything cuts short the attack. Bleeding depresses the heart's action, and is favourable to the development of the epileptic state, and therefore it cannot tend to cut short the coma.

Epileptic coma, like traumatic coma, may go on for a very considerable time, and yet the patient will perfectly recover. As an instance of this kind I will refer to the case of Eliza Williams, a girl of 13 or 14 years of age, who was admitted into Augusta ward on the 26th of March last, in a state of profound insensibility, which continued till the 30th, a period of four days, and for a week afterwards in a less profound degree.

In this case the treatment was of the expectant kind. We kept this patient's bowels open, and attended to her general nutrition, taking care to avoid any causes which might operate injuriously on her. She recovered perfectly; had several epileptic fits afterwards, with coma of very short duration, and left the hospital much improved in her general condition.

There are, however, cases of coma in which more active treatment than this is required; as, for instance, in cases of coma arising from rheumatic fever, gout, or scarlet fever, or in coma arising from poisoning by urea, in diseased states of the kidney. In such cases it is very necessary to do something more than watch; your treatment must be of the eliminating kind, such as blistering and purging; at the same time, it is necessary to uphold the powers as far as the digestive organs will admit. When you have reason to believe that the blood is poisoned by urea, as in renal disease, you will frequently find the hot air-bath of service; and you must give drastic purgatives, such as elaterium, or the compound powder of jalap, or the Iberis amara. In fine, as a general rule in the treatment of the comatose state which does not arise from pressure, you must bear in mind what I think I have made out in these lectures,—namely, that delirium is the slighter degree, and coma the more aggravated condition of the same state; hence, in a great measure, the treatment of the two conditions must be similar; for coma and delirium differ from each other in degree, the former being only an advanced stage of the latter affection.

Original Communications.

PARTIAL DISLOCATION OF THE
RADIUS AND ULNA
BACKWARDS,

WITH THE FORMATION OF A NEW JOINT.

*Read before the Abernethian Society,
March 14th, 1850,*

BY T. M. GIRDLESTONE, F.R.C.S.

THE preparation here described was taken from a subject in the dissecting-rooms, and is consequently without a history; but, from the appearance of the joint, we may conclude that the displacement occurred some years before death.

The forearm could be flexed to a right angle, but was here stopped abruptly by an unyielding barrier in the joint: extension was but little impaired; rotation somewhat limited: none of the muscles were torn, but those in front of the arm and forearm were wasted.

The following is the condition of the joint:—The anterior ligament had been ruptured, but a part of it remains, and has formed fresh attachments; the lateral ligaments have suffered but little injury; the orbicular ligament has been torn across, and the posterior portion of it passes obliquely upwards over the head of the radius, and terminates in the external lateral ligament, which is thus lengthened; while the anterior portion has become adherent to the neck of the radius, and limits its rotation outwards. The posterior ligament has acquired an attachment to the old articular surface of the olecranon, and is considerably strengthened by some strong transverse fibres which are attached to the condyles, and appear to prevent the coronoid process of the ulna from slipping into the olecranon cavity of the humerus.

The coronoid process of the ulna, rounded at its extremity, and flattened on its articular surface, rests on the margin of the olecranon fossa, at the back of the articulation of the humerus, and is here supported in a new joint, which is formed by some irregular-shaped pieces of bone developed in the posterior ligament, as well as by a con-

siderable prominence of bone growing from the back of the inner condyle. The head of the radius rests on a similar process behind the outer condyle.

The ends of the bones entering into this new joint are smooth and hard, and covered by a substance resembling a thin layer of fibro-cartilage, excepting the head of the radius, which is but little altered, its cartilage remaining on it, and giving rise to some fibrous tissue which is attached to the cup-shaped cavity on its summit. A thin layer of cartilage, with some tough fibrous tissue adherent to its surface, covers the old articulation of the humerus. The radius and ulna are not separated from each other.

When the bones of the forearm are driven backward from their articulation with the humerus, they do not always occupy the same spot; for the coronoid process of the ulna may be drawn upwards and slip into the cavity, at the end of the humerus, destined for the reception of the olecranon, or it may remain between this cavity and the centre of the trochlea over which it has passed: thus the dislocation may be complete or partial. On examining the bones of the elbow-joint we might be led to suppose that a partial dislocation backwards was impossible; and, indeed, it is not recognised by several eminent writers, among whom are Sir Astley Cooper and Boyer. The latter says—"Dislocations of the forearm backwards can never be incomplete." And several modern authors, in describing the numerous luxations to which the elbow is subject, invariably state that, in dislocation backwards, the coronoid process of the ulna occupies the cavity formed for the olecranon. Now this is by no means so constant; and I believe, if we examine carefully the seat of the bones in these dislocations, we shall hardly find two cases precisely alike, although there are many in which the coronoid process does not occupy this fossa.

In the Dublin Quarterly Journal for May 1848, Dr. M. H. Stapleton relates three cases of partial dislocation; one of the ulna alone, and two of both bones backwards, which came under his notice, and were easily reduced.

In determining that these were cases of incomplete luxation, Dr. Stapleton was guided by the projection of the

olecranon backwards, which was less than it would have been had the displacement been complete: but what he chiefly relied on was the relation this process held to the inner condyle,—a feature by which we may determine whether the luxation is complete or incomplete. And he here follows the rules laid down by Malgaigne, who states that, in partial dislocation, “the coronoid process of the ulna lies upon the inferior part, and a little posteriorly to the pulley or trochlea of the humerus; the fore-arm is scarcely at a third of its flexure, the olecranon process is an inch and a half behind the inner condyle, but upon an horizontal plane perceptibly inferior to it; whilst in the complete dislocation, the coronoid process of the ulna being lodged in the cavity usually occupied by the olecranon, the olecranon is found almost equally distant from the inner condyle, but evidently superior to it.”

We may easily satisfy ourselves of the truth of this assertion by placing the coronoid process of the ulna (of the dry bones) first on the back of the trochlea, then in the fossa just above it, at the same time keeping the arm partly flexed. This appears to me to be a diagnostic sign, which, in many cases, may be practically applied. In partial dislocation, when the arm is semi-flexed, the olecranon is in the same *horizontal plane* as it would be if the ulna were in its natural position,—that is, “level with the external condyle of the humerus, and inferior to the internal” (Boyer); but the olecranon, though in the same plane in both cases, is much nearer to the inner condyle in the natural position than in dislocation.

There is a preparation in the museum of the hospital (3. 33.), of an unreduced luxation which very much resembles the one here described. In both instances the coronoid process of the ulna is not in the olecranon cavity, but on its margin, and supported by a growth of bone springing from the back of the humerus; and in both the olecranon is *inferior* to the inner condyle: thus agreeing with Dr. Stapleton's cases, and the rules laid down by Malgaigne. I may add, that the latter author gives it as his opinion “that the incomplete dislocation is by far a more frequent occurrence than the complete.”

We ought not to be surprised to see the coronoid process remaining on the

back of the trochlea of the humerus, when we find some of the lateral ligaments and the brachialis anticus muscle remaining entire; for the former would be put on the strain, and tend to hold the bones in this position, while the latter must be ruptured if the ulna pass further upwards and backwards.

The fore-arm in these injuries may be either supine or prone. In those cases which came under the notice of Sir A. Cooper it was supine, while other observers have found it in a state of pronation.

The heaping up of new bone in the neighbourhood of an unreduced dislocation is stated by Cruveilhier to be common in the hip, but rare in the elbow-joint. It has taken place, however, in this case, as in the one in the museum: and there is one preparation in the Museum of the College of Surgeons (Patholog. Cat. vol. ii. p. 208), where “the radius and ulna are dislocated outwards, and *partially backwards*: the ulna is fixed to the humerus by bone.” Cruveilhier, also, in his *Plates of Anatomy and Pathology* (Liv. ix. Ch. iv. p. 8), gives the representation of an unreduced complete dislocation of the radius and ulna backwards, with a shell of new bone adhering to the radius and ulna near the joint, and projecting for some distance up the arm in *front* of the humerus, where it must have assisted in fixing the dislocated bones in their abnormal position.

Since writing the above I have seen a little girl in whom the same accident, attended by precisely the same symptoms, has been observed. The patient is now in St. Bartholomew's Hospital, under Mr. Stanley. The accident happened four months previous to her coming to the hospital, and, not being reduced, the bones became fixed in their new position.

CONGELATION OF PROTOXIDE OF NITROGEN AND ALCOHOL. BY M. DESPRETZ.

A PORTION of protoxide of nitrogen in the fluid state being poured into a platina capsule placed on a brick, under the receiver of an air-pump, became, by the first few strokes of the piston, covered with a white stratum, and was quickly converted into a snow-like mass of white substance. In a similar manner alcohol, mixed with protoxide of nitrogen, solid carbonic acid, and ether, was solidified, although imperfectly. —*L'Union Médicale.* x

CASE OF
UNUNITED FRACTURE OF THE
TIBIA,

OF TWENTY-FOUR YEARS' STANDING,
SUCCESSFULLY TREATED.

By R. W. TAMPLIN, Esq.
Surgeon to the Royal Orthopædic Hospital.

Miss —, æt. 25, at the age of fourteen months slipped between the bars of a garden-seat. The only circumstance which attracted attention was a broad discoloration at the lower third of the leg, and a slight curvature of the bone. After a few weeks the child was noticed to walk less strongly, when a surgeon was called in, who consoled the parents with the assertion "That there was no necessity for uneasiness, as many children had a difference in the straightness of their legs at that age." And upon the mother's remarking that such had not been the case until the bruise was noticed, replied, "That all would be well in a few months." Friction and bathing were resorted to for some time, and the child is stated to have walked without limping until she was three years old. Her manner of walking then became irregular, and the bone was noticed to project, which was supposed to arise from her increased weight. Another surgeon was now consulted, who discovered the fracture, and pronounced the bone to have been "falsely united." An endeavour was made to rupture the false union, but without success. Frictions and ointments were again used, with a view of obtaining absorption of the extraneous matter, and the part supported by plaster. The case appeared to be progressing satisfactorily, when the child met with another accident, and the smaller bone of the leg is stated to have been broken. Splints were then applied. From nine years of age the leg was supported by an instrument, and crutches were occasionally used. The spine is stated to have been also curved at this time. Her general health became impaired, and constant suffering was occasioned by any attempt at walking.

The patient was now placed under a physician, since deceased, who especially treated spinal cases. The uniting medium is stated to have been broken

by that gentleman, with the view of reducing the fracture, and forcible extension had recourse to, which brought the leg down for the time being, but it always returned to the malposition. This treatment was continued for two years, and then the case pronounced "incurable." The patient was at this period eleven years old. The leg was placed in splints, which were continued until she was fifteen; but she was unable to put the foot to the ground. Many surgeons of eminence were consulted, and amputation was the general advice. An instrument was then obtained to hold the knee and ankle stiff, with a high-heeled boot, and the leg supported by a case of sole leather from the knee to the ankle: with this she managed to get about, but not without great pain; the weakness increasing in spite of the artificial support.

On the 17th of July, 1849, I first saw the patient, and, upon examination, found that the leg had been fractured at the lower third obliquely upwards, the upper portion of the tibia projecting pointedly forwards, and riding over the lower third. The leg was two inches and a half shorter than the other. It was freely moveable. The knee, from the constant irregular strain upon the ligaments, yielded outwardly, and the patient could not put the leg to the ground, even with the assistance of the support, without suffering severe pain both at the point of fracture and in the knee-joint. Her general health had suffered more or less, and her existence is stated to have been a burthen to her.

From the history of the case,—the fact that it had existed from childhood, that all attempts had failed, that amputation was the general advice given,—I gave a doubtful opinion, but determined to make an attempt to obtain a union without operation. Three indications occurred to me: first, to bring the bones in apposition; the second, to obtain absorption of the false uniting medium; the third, to endeavour to obtain union, either by the deposition of bony matter, which I thought might possibly be thrown out from the irritation which must necessarily be set up, or by a contraction of the portion of the false union which immediately surrounded the fracture. With these views I ordered an instrument to be so made that the thigh could be firmly grasped above the condyles of the femur, the

foot below having a screw by means of which the distance between the knee and foot could be gradually increased. This instrument was applied on the 31st of July, 1849, and the leg kept horizontal, in the extended position. Gradual extension was now commenced, and continued for four days. So much pain was occasioned in the gastrocnemius, that I found it necessary to divide the tendo-achillis, which was done in the usual manner by puncture from within outwards. The instrument was omitted for eight days, and then re-applied, and extension again used. From this time the leg became gradually and easily elongated; and during the extension a steady continued pressure was kept up on the tibia above the point of fracture, and counter-pressure at the back of the leg, just above the ankle-joint. This treatment was persevered in unremittingly until the 9th of January, 1850, without interruption to the health,—there was, however, at times severe pain, which was allayed by opiates,—when, upon examination, the leg was found to be of equal length with its fellow, and the bone retained its position unassisted. I then applied the common splints, and ordered an instrument, with a boot attached, to support the weakened knee-joint, which had resumed its proper relative position during the treatment, and also having a pad to support the tibia, in case the union was imperfect.

On the 26th of February, the patient could raise the leg in the horizontal position without the slightest pain, and without a sign of motion at the point of fracture. I then applied the new support, which was worn, without any attempt to put the foot to the ground, until the 8th of March. She was able to stand on the 3d April, and then, at the request of Mr. Travers, and afterwards in the presence of Mr. Lawrence, both of whom kindly visited the patient, she walked without pain, and without a sign of motion at the point of fracture. Since that time she has continued to use the leg freely, with slight intermissions from indisposition. Can walk up and down stairs. Her general health has improved, and I have every reason to believe that a perfect cure has been effected.

22, Old Burlington Street,
July 1850.

A CASE OF PROBABLY

INTRA-UTERINE ACUTE INFLAMMATION OF SEROUS MEMBRANES.

By W. B. KESTEVEN, ESQ. M.R.C.S.

Meningitis—pleuritis—peri- and endocarditis—pneumonia.—Death of the infant.—Spasmodic disease—and hemiplegia in the mother during pregnancy.

THE following case presents several points of practical and pathological interest. These I have endeavoured to point out in the observations which follow its recital, as they furnish the reasons for placing it on record in the pages of the MEDICAL GAZETTE.

A male child, born Feb. 17th, 1850; the labour, which was a first labour, was natural in every respect, and had occupied about fourteen hours. When born, the child, which was large and well-formed, did not breathe without the employment of the usual means for rousing apparently still-born children. Its cry, when these measures had established the act of respiration, was not as loud and strong as is common to children of an equal size, and as fully and well developed. The breathing was quick, and appeared as if performed by the shoulders rather than by the ordinary thoracic movements. There were very visible depressions above the clavicles during each inspiratory act. The cry was a sort of paroxysmal effort—he seemed to cry as if in bursts of passion. In the intervals he laid very quiet, with the exception of an occasional short dry cough. He took the breast, but always with some trouble. His intestinal and urinary excretions passed as usual.

On the fifth day he refused the breast: he had seemed to flag a little on the preceding day. The breathing now became still more frequent; the pulse was so rapid and feeble that it could scarcely be felt, and could not be counted; the action of the heart was so tumultuous, and its impulse so considerable, that the sounds were rendered indistinct. The respiratory murmur was loud all over the chest.

On the sixth day the symptoms continued the same. The nurse, an experienced, sensible woman, spoke of the

child's having been slightly convulsed; that it had stretched out its limbs now and then, and rolled its eyes about in an unusual manner. Dr. Robert Lee having been called in to see the child's mother on this day, saw the infant also, considered that he was only suffering from want of nourishment, and recommended a wet nurse. This advice was followed, but the child would only suck twice. He had been fed pretty much with milk and water, as the mother had not a very full supply of milk, and the infant had not taken the breast readily. No vomiting occurred.

In the course of the seventh night a severe and long convulsive fit occurred, accompanied with a peculiar and distressing cry. Convulsions now occurred several times a day for the next two days.

On the tenth day the child died in a fit, which had lasted several hours.

Assisted by my friend and neighbour, Mr. Thomas Graham, the post-mortem examination was made sixteen hours after death. The entire surface of the brain presented effusion of serum and yellow lymph in the meshes of the pia mater beneath the arachnoid membrane. The lateral ventricles contained each about a drachm of serum. The substance of the brain presented nothing morbid, except that it was perhaps a little firmer than usually met with in infants.

The surface of the medulla oblongata was thickly coated with fibrin, which was more abundant over the inferior than on the superior surface of the brain.

On opening the thorax, we found the pleural surfaces throughout adherent by recent soft yellow lymph; their cavities were completely obliterated. The two surfaces of the pericardium were also universally adherent by the same kind of lymph. The endocardium had not escaped; for, on closely examining the aortic valves, minute, transparent, colourless, and quite soft granulations were discovered on their edges.

On cutting into the substance of the lungs, the lower lobes were in a state of semi-hepatization; their structure dense and friable, but not without a slight degree of crepitation. In some parts they had a tough feeling, and when thrown into water remained suspended just beneath the surface, and in physical characters resembled what is called atelectasis.

The bronchial mucous membrane was of a deep red colour.

REMARKS.—The following points of interest are observable in this case:—

1. The probability that these diseases had their commencement during intra-uterine life.

2. The great extent to which acute inflammatory disease was developed in so young a child.

3. The degree in which the symptoms indicated such pathological conditions.

In tracing this extensive inflammatory disease to the period of intra-uterine life, we have to consider the history of a pregnancy and labour also possessing pathological interest. The following are the facts of the case:—

The mother of this infant is an apparently healthy young woman, about 23 years of age, of rather a full habit, but who had always enjoyed good health, with the exception of dysmenorrhœa at the catamenial periods. She was married in May 1849, and soon afterwards became pregnant. She suffered much more than usual from sickness, and an irritating cough, even up to within a few weeks of labour.

In the month of October, without any discoverable cause, she was attacked with severe cramps of the uterus, conjoined with spasm of the diaphragm. The pain of these cramps and spasms was most excruciating. The attack lasted fifteen hours without any amendment, notwithstanding the most active treatment. So agonising was the pain, and so distressing was the interruption to the respiratory movements, that I verily thought she would have died in some of the paroxysms. In a few days, however, she was restored to her former health.

On the 2d of January she suddenly lost her consciousness for a few moments: at the same time the sensation and motion of the right side and extremities disappeared for several hours. Numbness and tingling of the limbs, however, continued for several days. The pulse, it must be observed, was full, but not hard. The heart's impulse and sounds were perfectly natural. Active antiphlogistic treatment was adopted, and very low diet rigidly adhered to up to the end of gestation.

On the afternoon of the 17th February labour was suddenly ushered in by severe rigors, intense headache, and

pains in the limbs and back. The pulse was 140, and full. I attempted to bleed her from the arm, but could not by any means obtain sight of a vein; and, as the labour-pains began to manifest themselves most decidedly and quickly, and as she had been previously reduced by the means already stated, I did not prosecute the depletion.

The labour was in every respect natural, and terminated in about fourteen hours.

At midnight of the same date I was summoned to her in great haste, and found her in a paroxysm of puerperal mania: the countenance flushed; the surface of the body bathed in a most profuse perspiration: the pulse too rapid to be counted, it must have been nearly 200, and feeble: there was some little tenderness over the uterine region; the bowels had been opened; urine had passed freely; the lochia were abundant. A full dose of muriate of morphia and of tincture of digitalis completely dispersed this formidable group of symptoms: she fell into a quiet sleep, and awoke after several hours as well as if nothing particular had taken place. The next day was passed without the occurrence of anything remarkable; but about 8 o'clock in the evening she was seized with an attack of spasms resembling those from which she had suffered in the previous October,—with the difference, however, that this last attack yielded to remedies in four hours. Spasmodic pains in the right side of the chest continued for several days, and gradually merged into subacute pleurisy, producing effusion into the pleural cavity. Absorption of the effusion readily took place under the use of mild mercurials and counter-irritation, and the patient completely recovered.

The consideration of the history of this pregnancy and labour shows the existence of a disposition to excessive vascular action, and a morbid condition of the blood itself; and affords every reason to conclude that the maternal diathesis was transmitted to the foetus in utero in such intensity, that acute inflammation of the serous membranes was excited before birth.

This morbid condition of the blood in the pregnant female is a fact in physiology; but it is a source of some regret that in this particular case an analysis of the blood was not made. The occurrence of such an amount of disease,

however, in the infant, could never have been anticipated, and therefore the urgency of such an analysis was not apparent. It must be added that this lady had suffered considerable mental anxiety during her pregnancy.

2. The extent of disease here recorded is, so far as the author is aware, unparalleled, regarded as intra-uterine, and of extraordinary extra-uterine rarity in an infant of ten days old. The writer has searched through a great many of the first authorities, and can find no record of such an extent of such disease in so young an infant. The only case at all parallel, which he has met with, is one of an infant four days old which died of pneumonia, and is recorded by Dr. Casper, in his "Wochenschrift," Nov. 1849, in an article on the causes of death in new-born infants. Dr. Casper there observes that the appearances of pneumonia, as shown in new-born infants, so closely resemble those of the condition termed atelectasis by some pathologists, that he is disposed to think the latter has been mistaken for the former. The case now detailed presented the same feature, and favoured the same conclusion.

3. With regard to the disproportion between the amount of actual disease and the symptoms which were manifested, it may be observed that it has been pointed out by Billard, that in new-born infants the absence of febrile reaction under the most severe and acute inflammatory disease is a law which contrasts strikingly with the opposite condition in infants after the period of dentition.* Certainly such law alone can explain the existence of such extensive disease for the period of this infant's life with so few symptoms; since the state of the respiratory functions, of the pulse, &c., was not more abnormal than is often observed in feeble children.

Holloway, June 1850.

RUPTURE OF THE DUCT OF STENO.

A BOY was exhibited in whom this accident had taken place from a blow. No external fistula was formed, but a tumor, half as large as an egg, had accumulated from the effusion of saliva under the cheek. This was punctured by Dr. Pepper with a trochar. The tumor returned in a few days; but the patient was lost sight of.—*Dr. Hartshorne, in American Journal of Med. Sciences*, Jan. 1850.

POSTSCRIPT TO SOME
OBSERVATIONS ON THE
CONDITION OF THE BODY
AFTER DEATH BY
CHOLERA,

BY MR. FREDERICK BARLOW, M.R.C.S.

In quoting Dr. Dowler on the subject of post-mortem temperature (see *MEDICAL GAZETTE*, July 5, 1850, p. 20), I have made an error which I wish to correct. I have stated that the temperature of the internal parts does not appear to have been observed; but I find, on reading the "Researches," the two following cases:—

"W. O., an Englishman, aged 27; dead five hours; neck moderately stiff; brain 93°; epigastrium 100°; chest 93°; thigh 99°; the arms strongly contractile, &c."

"J. H., an Irishman, aged 36; of gigantic frame, estimated at 200 lbs. In fifteen minutes after death the neck, jaws, and recti muscles were immovably fixed, the contractility of the arm being very powerful. In an hour and ten minutes the rigidity became universal, the thigh being at 107°. In one and a half hours the epigastrium was at 106½°, and the brain 101°."

The following is the account of the case whereto I have referred briefly, in which a rise of temperature appears to have taken place after death:—

"J. K., a Philadelphian, aged 25; in fifteen minutes after death, presented the contractile phenomena in their most intense form, but which declined wholly in one hour, the body being everywhere flexible. In half an hour after, rigidity set in. This body, which before death had been remarkably cold, had a temperature after death as high as 109°, and which did not refrigerate below 104° in three hours after."

Dr. Dowler makes the following observations in reference to post-mortem heat:—"The continuance of, or rather the degree in which post-mortem heat is evolved, bears no proportion, I repeat, to the intensity of post-mortem contrac-

tion. The great heat developed in the dead body I have endeavoured to illustrate in the medical journals of our country, and will not, therefore, dwell upon that subject at present. I find, however, on examination of the original papers not yet published in detail, that for the most part, when the heat had declined, the contractility was exhausted; but that the presence of great heat, ranging as high as 113°, did not by any means imply the presence of contractility nor the absence of rigidity. Authors seem not to have been aware of the augmentation of animal heat after death. Some have, it is true, noticed an increase of heat after death from cholera, compared with the extreme coldness of the surface during the last hours of life; but has any one hinted that this post-mortem heat ever rose as high as even the healthy standard,—to say nothing of 14° or 15° beyond that?"

It is quite obvious how extremely cautious we should be in using the words *rise* of temperature, as applied to the dead. The heat tested, *at the time of death*, by the thermometer in certain parts, should be compared with that manifested by the like means in the same parts at given periods afterwards. The colour of the surface, and whether it undergoes change or not, should be observed; the state of the body as to perspiration, or the absence of it, should be noticed particularly. Different parts of the surface should be compared as to heat; and the temperature of the skin and internal parts should be contrasted. The mucous membrane of the lower bowel might be examined without any incision being made.

The greater part of that which I have written on the subject, I have, in the desire to cause inquiry, written not positively, but *suggestively*. It is time that our knowledge of the alleged rise of heat in the dead should be more exact. The high temperature noticed by Dr. Dowler some time after death is of great interest; and, though it were shown to be the remains of heat generated in life-time, it would be so still. The highest temperature which I have observed in the dead is 104°. The observation was made on the axilla of a man who had died of apoplexy. There were well-marked muscular contractions seen also: I hope to detail them in a future contribution.

I find the parts tested by the thermometer by Dr. Dowler have been more

* See *Experimental Researches on the Post-mortem Contractility of the Muscles, &c.* By Bennet Dowler, M.D.

† I have concluded from the context that such phenomena are alluded to as may be excited by percussion.

frequently specified than I supposed. And I must conclude by the remark, that, though I differ from this writer in many of his conclusions, and dissent from the criticism in which he has indulged, the phenomena he has narrated are extremely well worthy the close attention of physiologists. Mr. Helps has already repeated Dr. Dowler's remark on the ease with which post-mortem contraction may be excited by *percussion*; and a careful inquiry into the condition of the dead as to the state of their temperature, might be found to confirm the accuracy of the observations, if not the correctness of the inferences, of this inquirer.

PROGNOSIS IN ANGINA PECTORIS.

THOSE authors who consider angina pectoris as depending on the organic lesions of the heart and its vessels so often found in it, of course regard it as a disease necessarily fatal. As we consider it a nervous disease, depending on a morbid condition of the par vagum, we should make a different prognosis, particularly if the affection be not of long standing, and the patient be young and healthy. We think it an error to suppose it peculiar to advanced age; it may occur, like other neuralgia and rheumatism, at all ages, and in such persons may be cured by similar remedies. There are, even among old people, several undoubted cases of cure recorded in the Dictionaries of Medicine. Allowing for inaccuracies of diagnosis, we may find Laennec not very far from the truth when he says—"Angina pectoris, in a light or moderate degree, is an affection extremely common, and exists very often in persons who have neither an organic disease of the heart nor of the great vessels. I have seen many who have had very violent attacks, but of short duration, who have recovered." (*Auscult.*, tom ii. p. 747.) If the disease be neuralgic, recovery may be complete without any organic change. If it be rheumatic, recovery might leave behind it a predisposition to cardiac disease, so often found in connection with it. Even supposing the disease to arise from a complete disorganization of one pneumogastric, life may be considerably prolonged, and good health enjoyed—the nervous communication being kept up by the anastomosis between the superior and inferior laryngeal, which has been found one-third the size of the cervical par vagum.—*Dr. Kneeland*; in *American Journal of Medical Sciences*, Jan. 1850.

FACTS AND ARGUMENTS IN SUPPORT OF THE CONVULSIVE THEORY OF MENTAL DISORDERS.

BY WILLIAM SMITH,

Member of the Association of Medical Officers of Hospitals for the Insane; formerly Resident Surgeon in the Lincoln Lunatic Asylum, and subsequently in the General Hospital at Lincoln.

THE more deeply I reflect upon the interesting phenomena of mental derangement, and the more attentively I peruse the recorded opinions of eminent authorities on the Diseases of the Brain and Nervous System, the more strongly am I convinced of the truth and correctness of my former proposition, that the whole class of mental disorders ought to be viewed as true convulsive or spasmodic affections, and treated as such; and, moreover, the present humane and enlightened mode of practice, now adopted and pursued in our best regulated lunatic establishments,—which places little faith upon mere medical applications, and relies almost exclusively on moral, regimenal, and dietetic remedies,—strongly corroborates this view of the subject. Nay, I will even venture one step further, and assert my belief, the result of considerable personal experience of such affections, that great benefit would accrue to society, if practitioners, in the treatment of what are usually termed nervous disorders, would take a hint from the experienced superintendents of our public lunatic institutions, and eschewing the present routine wholesale and indiscriminate administration of drugs and pharmaceutical appliances, allow their patients the benefit of fresh air, exercise, plain, nutritious, unstimulating diet, and mental as well as physical occupation. Notwithstanding the eager thirst for knowledge, so clearly characterising the present age, the public generally, and, it is to be feared, the medical profession themselves (in too many instances), are grossly ignorant of the organic laws which an all-wise and benevolent Creator has imposed upon living matter. Were that excellent and lucid work, "Principles of Physiology, applied to the Preservation of Health," by Dr. Andrew Combe, more attentively perused by the public and the profession, a large amount of dis-

ease, and consequent misery, might be prevented. Dr. Wm. Bush, in an excellent essay, contained in the 7th number of the *Psychological Journal*, remarks:—"In proportion as the improved sciences of physiology and pathology add to our knowledge of the essential elements of health and disease, they cannot fail to excite alarm in every reflective mind at the accidents so likely to accrue to the delicate and mutually dependent tissues of the body, and either to derange their functions in health, or to destroy their structure in disease. If this be found true in the general anatomy of the body, how much more applicable must it be where the minute tissues and intricate fibres of the brain are involved? an organ so sensitive to morbid influences, that its functions will be impaired, or altogether destroyed, by causes so subtle as not to be detected on post-mortem investigation. But the alarm which a review of these facts would naturally engender, is swallowed up in surprise on observing, that the functions of so delicate an organ are not more frequently and more seriously deranged by the turmoil of life, and the incessant demands which commercial and literary competitions make upon our energies. It is indeed true, that the consequences of these excessive mental demands are not always visited upon us in our own persons, but are reserved for more condign punishment in their infliction on our children, who become living and lasting judgments before our eyes, at the same time that they convey lessons of amendment to the present, and of caution to the future generation.

"If we more duly reflected how often with a name or fortune we transmit to our children the terrible nervous affections (and sometimes even the fatal seeds of family extinction) which they inherit from the exhaustion of our own energy in the gaining of these vanities, we might be induced to attribute more real happiness to health, virtue, and longevity, than to the pursuit of worldly gain, or to a conformity with the existing errors of our whole social system."

Do not these remarks apply to mental disorders with quite as much force as to the neuroses, or those of a convulsive or spasmodic character? The nervous system, in all, is at fault, and what matters it whether the cerebral, the spinal, or the ganglionic division be the

one mainly implicated? Do we not find, in actual practice, amongst these disorders, that the same grand fundamental principles of therapeutics direct us in the choice of our remedies in all of them? There is in all nervous diseases a want of tone or natural vigour in the system, a disturbance of the natural equilibrium between the nervous and vascular systems; a general intolerance of blood-letting, or powerful depletive or evacuating measures of any kind: strong purgatives even are invariably prejudicial, and though the momentum of the blood may appear to be, and probably is, greater than natural, and the pulse increased in frequency, as in the *clavus hystericus*, or during a maniacal paroxysm, still these alone, or even combined, are no proofs of actual power, any more than the raving delirium of fever, or the temporary excitement or exaltation of intoxication, denote increased tone of the natural powers.

The idea occurred to me the other day to consult Johnson's Dictionary as to the precise signification of the word convulsion. That erudite lexicographer thus defines it:—"A convulsion is an involuntary contraction of the fibres and muscles; an irregular and violent motion, commotion." Now, does not this description singularly apply to the maniacal paroxysm? The patient, however he may desire it, for we have ample evidence to prove that many strongly resist the insane inclination, and even warn their attendants of the impending storm, cannot control the overpowering and impetuous impulse of thought or action; volition or the power of the will is wholly in abeyance for the time: the reasoning faculty, which at other times reigns supreme, and presides over all the feelings, thoughts, sensations, actions, &c., restraining the lower, grosser, and more animal propensities of our nature, is, during the paroxysm, dethroned from its high estate, and "all the jarring passions are at strife." Thoughts, ideas, emotions, the various nerves of special sense (it may be one, several, or all of them), the secretions—under the immediate control of the ganglionic system, but yet subject (as governors of petty provinces under the absolute authority of a reigning monarch) to the one great controlling power, the sensorium—take on irregular or abnormal actions.

Numerous arguments might be adduced to prove the intimate connection and natural affinity existing between mental disorders and the whole class of convulsive and spasmodic diseases. One probably more striking than the rest I will mention here—viz., "the tendency of these morbid actions to distinct intermissions of longer or shorter duration, and more or less perfect in kind." Dr. Henry Holland, in an interesting chapter, "on morbid actions of intermittent kind," has some remarks which I consider peculiarly applicable to the question now under consideration. At page 329 he observes—"This tendency to intermission in the animal functions may justly be termed a law, inasmuch as it is natural, general, and manifestly designed. All the phenomena of mind, and those of body which have direct relation to mind, are more or less submitted to it. The alternation of sleep and waking, a phenomenon in which so many separate functions have part, and by which all are regulated and controlled, is the instance at once most familiar. Each organ of sense is more or less connected with this one important condition of existence, while they have, besides, various shorter and more irregular intermissions, depending on changes in the action upon them from without, and the proportion of this action to the excitability they possess." If we admit the truth and accuracy of these propositions, as applied to some forms of nervous and spasmodic disorders, is it philosophical, or in accordance with common sense, to deny their application to mental derangement, which is supposed to be an affection simply of another portion of the nervous centres? One cause of the endless disputes amongst physiologists, and ever-varying and discordant theories advanced by different authors, relative to the laws and action of the nervous system, is mainly to be attributed to the infinite divisions, subdivisions, and arbitrary distinctions which have been made with regard to that portion of the human frame. Had the illustrious Harvey puzzled his brains with such an infinitesimal arrangement of the blood-vessels and vascular system, that great boon to science and mankind, the discovery of the circulation of the blood, might still have remained buried in oblivion. Mr. Travers, the experienced surgeon to St. Thomas's Hospital, who

may be justly looked upon as the Nestor of modern surgery, has remarked, in his *Further Inquiry concerning Constitutional Irritation*—"In the rapid progress of all subjects of scientific inquiry during the last twenty years, that of physiology seems to have fully participated. The renewed intercourse between the nations of Europe stimulating, by the quick circulation of knowledge, a spirit of national emulation, has rendered the present age prurient of discovery; and it is not without some apprehension for their stability and value, that I observe the credulous reception and ready adoption, by the physiologists of this country, of the results of experimental inquiry on the continent. It is enough that a name of some celebrity stands connected with them, to obtain currency for many statements startling by their novelty, and reasonings irreconcilable with our previous observations and opinions.

"Some physicians, confessedly men of great learning and talent, little accustomed to the details of healthy anatomy, and unacquainted with the visible changes of living structure forced upon the surgeon's attention, have innocently contributed to the encouragement of crude theories and fanciful distinctions; add to this, a tendency to hypothesis is begotten by the obscurity in which the medical department of pathology is necessarily involved. The microscope, the means of discovery most commonly resorted to, is a most prolific source of delusion, judging from the strange and discordant appearances which it presents to the eyes of its different employers. I read that the globules of the blood are gaseous vesicles, whether of carbonic acid or atmospheric air, and imbued with the property of moulding their own vessels in a layer of coagulum; of the exudation of lymph of pus; of the separation of the colouring matter from the globule of blood actually taking place in the vessel, and thus constituting one of pus; the organization of a clot of blood; the formation of an entire organism—blood-vessels, absorbents, and nerves—in a floating layer of fibrine, wholly detached from all surrounding parts; the branching forth of new canals through the cellular texture, from the continuous sides of inflamed vessels; the transportation of pus by the veins from remote lesions, abscess or ulcer, to parts

free from any other sign of diseased action, as the parenchyma of the lungs, or the parietes of the heart, &c.;—these things, and a thousand others not less extraordinary, may be; yet if knowledge has no bounds for our senses, its advancement must keep some measure with our understandings, or it ceases to be useful. It is impossible to contemplate the present travelling rate of physiology, and the mass of unsatisfactory experiment and undigested speculation continually throwing up, without a feeling of sympathy with the hopeless perplexity of the student, in such an '*embarras de richesses*,' and, what is vastly more serious, some alarm at the possible consequences that may result to the usefulness and credit of the profession of medicine, and the health of the community."

In proof of the correctness of my views relative to the real nature or essence of mental derangement, I shall take leave to quote some extracts from the lately published Annual Report of the Lincoln Lunatic Asylum, for the year 1849. Everything which has emanated from that establishment, in the shape of Annual Reports, &c. bears the impress of extensive observation and acute discrimination, and has a decidedly practical bearing upon the welfare and happiness of the insane. The Governors, under the head of violence, remark:—"This difficulty is the point of view in which insanity has popularly been considered, and very little has been done by the profession to show the extreme exaggerations upon the subject. Violence is not the common characteristic of insanity; it is the exception; it seldom appears, except at intervals, and is very rarely of a sustained character. In common life there are great varieties of temper, and some are habitually violent; and a vulgar extension of the idea has encouraged a notion, that violence in the insane is to be subdued by terror, or chains, or in any way except by management. Two principles, however, ought to have suggested themselves;—that confinement will increase the irritability and violence of a man, as it would of a dog;—and also that confinement facilitates the ill-usage of patients, by making it perfectly safe to the attendant, and so additionally tends to increase that irritability. . . . "It is very obvious that exercise in the open air, a variety

of engagements, and considerable freedom of range, must tend to divert the mind from a tendency to violence, and diminish the irritability of the system. . . . Nine-tenths of the erroneous treatment of insanity has arisen from confounding insanity with phrenitis, or inflammation of the brain, a disease requiring remedies usually wholly contra-indicated in the treatment of the insane; and the same remark may be applied to cases of delirium tremens; the former introducing, among other proposed remedies, blood-letting, and shaving the head; and the latter the use of opiates. . . . "It is remarkable to observe how soon after admission the more exaggerated aspects of the disease seem to relax in this house. Every facility is offered for innocent outlets to the excitability of the patient, through the free use of his bodily organs. Exercise and other occupation in the grounds, a free range from apartment to apartment, games without doors in fine weather, dancing within doors in wet weather, are substitutes for violence with many; nor is any interference attempted with grotesque attitudes or motions, or grimaces, or declamation, in which the patient may indulge for the purpose. The irritability is not concentrated or stimulated by compression. The danger from violent patients is found to be greatly increased, not merely by the increased tendency to violence, but by the diminution of caution and watchfulness, which a reliance upon instruments afterwards produces. That the tendency to excitement is increased by instrumental restraint would appear from the fact that cases of death from maniacal exhaustion have disappeared from the books, contemporaneously with the disuse of the instruments. . . . "Experience will suggest to attendants resources for meeting the difficulties, where they cannot throw themselves upon the coarse and ready expedient of an instrument. In this house lately an epileptic female patient was subject to such an extraordinary tendency to violence in connection with the epileptic attacks, that an additional nurse was required on her sole account. The head nurse, however, in answer to an inquiry, observed, that they had comparatively little trouble with this patient now, as they merely sent her out of doors on these occasions, when

the weather allowed, and that after walking about sometimes for several hours, she would return, of her own accord, composed.

"Violence in an insane patient may sometimes be a mere blind animal impulse, quite involuntary on the part of the patient; and it is obvious that the proper course is to prevent the patient from doing mischief, until the fit is over, never, in such a case of long continuance. The mischief is prevented, as the mischief of an epileptic or hysterical fit would be, under which no rational person would think of applying an instrument. In the majority of cases the violence is semi-voluntary, and it is remedial, to rouse the patient's self-control. The condition is brought on and aggravated by every species of harsh usage, contempt, or injustice; and this feeling must be increased by the use of instruments, under which the motive to self-control ceases, and the patient indulges himself in letting his mind loose to its impulses of violence, leaning as it were upon the instrument; while the contempt and ill-usage which a cowardly bystander may then safely exercise aggravate the case. The irritated rebound of an insane mind cannot be crushed; it must be evaded and diverted."

Do not the remarks contained in the last paragraph most distinctly and substantially corroborate the views which I have lately advanced on the convulsive character of mental disorders? and, moreover, by their allusion to the hysterical and epileptic paroxysm, is it not evident that the Governors of the Lincoln Asylum view insanity as a kindred affection? There is, in truth, a strong family likeness pervading the whole class of nervous disorders; the difference is one of degree rather than of kind. If we dealt with the nervous system and its morbid affections more as a whole or entity, and not as composed of separate and disconnected portions, each having an action independent of, and beyond the control of the rest, much of the confusion and uncertainty that now hangs over the treatment of these disorders—suggesting an empirical and hit or miss selection of pharmaceutical remedies, or a blind routine plan of treatment, and rendering it a rich field for the unprincipled charlatan or the self-deluding homœopathist, would at once be obviated.

Whatever professed writers of treat

tises on insanity may think proper to advance as to the specific or exclusive location of mental disorders in the vesicular or cineritious portion of the brain, I shall take leave to view them as affections wherein all the nervous centres, cerebral, spinal, and ganglionic, are more or less implicated; and wherein the blood—a component and indispensable element in every vital function or action pervading the human frame—must also be taken into the account. Everything we know of the phenomena of insanity,—the derangement or disturbance of the special senses, one or more of them,—the depraved or perverted state of the secretions, sometimes in excess, sometimes defective;—the morbid sensibility or entire loss of sensation;—the irregular and irrepressible movements of the muscular system;—the noisy vociferations, or the sullen torpor, and refusal to answer the simplest question;—the extreme watchfulness (pervigilium), or the drowsy lethargic state of semi-consciousness;—the brilliant coruscations of wit and fancy, or the non-consecutiveness of thought or expression;—the ravenous appetite and intense thirst, or entire refusal of food and drink;—the irretention of urine; the involuntary and liquid dejections, or the obstinate costiveness and hardened scybala, frequently requiring copious enemata for their solution and evacuation;—all clearly demonstrate to the observant mind, that not only every portion of the nervous system—cerebral, spinal, and ganglionic, but likewise the vascular and assimilative systems, are alike more or less implicated in the one disorder usually designated mental derangement or unsound mind. Mr. Travers, whilst discussing the intricate phenomena of morbid action (page 253 of his *Further Inquiry*,) remarks:—

"The class of motor nerves, which in a state of health are subject to the will, are variously affected by disease; deprived of their tonic power, the muscles become tremulous and incapable of executing their ordinary actions steadily, both of resistance and of motion, passive and active. This, which amounts to a partial paralysis, may arise from causes operating through the brain or from the brain—i. e., from the defect or disorder of the stimulus conveyed by the sensitive nerves, or from the disorder or dis-

ease of the nerves of voluntary motion, singly or in association, or of the part of the brain in which they have their origin. They may cease to be influenced by volition, and the muscles be in consequence motionless from the defect of the stimulus, or an obstruction to its course; or other causes acting as a more powerful motive stimulus, they may be taken from under the control of the will and rendered altogether involuntary. Thus spasm and convulsion are accounted for by an action over which the will has no control. This may emanate directly from the brain, as we see in injuries of the head, or from some new, extraordinary, and powerful motive stimulus acting upon it. Such an one is injury or irritation of the nerves of the cerebral, spinal, or sympathetic division. It may be partial and transient, as in the cramp of the gastrocnemius; or with intermissions, or diffused, as in epilepsy, infantile convulsions, and tetanus; or it may be continued and partial, as in chorea; or continued and diffused, as in the paroxysm of frenzy.

"This is an extraordinary motive impulse, both as to origin, and course, and kind, operating upon the voluntary muscular system. But the involuntary, though less exposed and less frequently excited, is not beyond its reach: hence spasm of the heart, of the diaphragm, of the stomach, and the intestines. The nerves of these organs are those which belong to both systems—the cerebro-spinal and the sympathetic; for we are, perhaps, more accessible to pain from derangement of the vital functions than of any; and though we are not conscious sufficiently to identify the sensation which the blood produces on the lining membrane of the heart, or of food on the stomach, or of air on the cells of the lungs, we are quickly sensitive to the defect of these necessary stimuli to the motive power, by the distress which it occasions throughout the system: and this must be conveyed by the same nerves which render their morbid affections painful. Independently of the pneumogastric, the sympathetic ganglion upon the sensitive nerves of the posterior column establishes the communication of the cerebro-spinal and sympathetic sensitive systems; and as the muscles under the guidance and control of volition, which, in the ordinary state of health, are excited by the cerebro-spinal system of sensitive nerves, in disease obey the sensitive nerves with-

out its superintendence; so the sympathetic system, which in health maintains a partial independence of the cerebro-spinal, and is the centre of its own sensitive impressions and motive impulses, in disordered or diseased states of these organs, propagates its impression, and involves the cerebro-spinal system in an active participation and sympathy with its distress.

"Yet, as we have observed, the nerves which are proper to the special function of any organ are not those which convey the general sensitive impression which is the source of pain: as the optic nerve is not susceptible of conveying any sensation but that of light, or the olfactory but that of smell, so the morbid impressions are conveyed by the sensitive nerves in communication with the organ—whether the eye, or the heart, or the stomach—to the brain; and thence arise the morbid actions, the involuntary motors being excited to action by the extraordinary and powerful stimulus of morbid sensation. And it is this partial substitution of the involuntary for the voluntary, and the voluntary for the involuntary stimulus, or, more accurately speaking, of the sympathetic for the cerebro-spinal, and this for the sympathetic stimulus, which constitutes the derangements of consent and of action which we see in extreme cases of constitutional irritation. We see the muscles of voluntary and involuntary motion, as of the limbs and the heart, the muscles of respiration and of locomotion, obeying other than their natural and accustomed stimuli. It is true that the heart in spasm does not act at the command of the will, as the voluntary muscles in spasm defy the will; but its actions are so violent or so feeble, so unequal and inconsequent, as to excite universal agitation, and the utmost efforts of the whole muscular system in support of respiration and circulation, so as in some instances to render their continuance almost an act of volition; in short, to render the exertions of the cerebral system, while its powers remain, so far predominant as only establishes the partial independence of organic life, which we witness in the phenomena of sleep and death. The influence of the emotions and passions of the mind over the organic actions are sufficient to show the cerebral power of interference with them under extraordinary excitement."

I have made these copious extracts

from the instructive and carefully digested observations of Mr. Travers, for a two-fold purpose: 1st, to corroborate (which, to my thinking, they do most satisfactorily) the convulsive theory of mental disorders, and their natural affinity to the neuroses, epilepsy, hysteria, chorea, &c. &c.; 2nd, to prove, by the multiplied experience and logical arguments of so experienced a surgeon and indisputable an authority, the intimate and inseparable connections which combine together and incorporate into one focus the several portions of the nervous system.

It appears to me that we cannot take a philosophical and comprehensive view of the phenomena of disease, or apply our remedies with any degree of rational or scientific precision, unless we constantly bear in mind the reciprocal and consentaneous action of the several nervous centres upon each other and upon the blood. Even in so simple an affair as a common abscess or boil we have the clearest ocular demonstration of the principle that the whole system sympathizes with the local affection: and how, except through the medium of nervous influence, could morbid sensations be transmitted from the periphery to the centre, and the cerebral or spinal impressions (as the action may be motor or reflex) communicated from the centre to the periphery? That the constitution does respond to local irritation we have convincing proof in the rigor accompanying, or rather preceding, the formation of pus, even in the most remote portion of the human body. How, then, shall we presume to locate mental disorders exclusively in the vesicular portion of the brain, when common observation, or the most superficial attention to the morbid phenomena present, must convince us that the whole nervous system—cerebral, spinal, and ganglionic—and likewise the vascular and assimilative apparatus, are implicated in the disorder?

I feel thoroughly convinced, from an extensive research and laborious inquiry into the anatomy, physiology, laws, and actions of the nervous system,—as propounded by Carpenter, Watson, Travers, Henry Holland, Calvert Holland, &c., &c.—that we ought to view the noisy vociferations, restless mobility, and intensely accumulated excitability and exaltation of the insane, simply as an effort of nature to throw off the *mater*

ies morbi; and that the only philosophical method of dealing with nervous disorders, whether insanity, convulsive or spasmodic affections, is (after first removing all extraneous sources of excitement, mental or physical, and regulating the morbid or perverted secretions) to allow nature free vent for getting rid of the superfluous pent-up morbid irritability, by muscular exercise, the most obvious and natural outlet for the nervous energy, cheerful and agreeable occupation, a plentiful allowance of pure air, regular hours of rising and retiring to rest, a careful avoidance of all sources of mental excitement or irritation, plain, nutritious, unstimulating diet, cold shower-baths, sponging the surface of the body (in females, the spine more especially) with cold water containing salt, &c. &c. By adopting such a line of practice, even if we do not cure our patients, our remedies will not undermine the constitutional powers like copious depletion, salivation, caustic issues, long-continued courses of powerful medicines, drastic purgatives, rigid confinement to the couch, sick chamber, &c. &c. The sound common-sense observations of Sir Benjamin Brodie (contained at page 265 of his *Lectures on Pathology and Surgery*) cannot be too strongly or repeatedly impressed on the junior members of the profession:—"No one can be constantly dosed with medicine without the health being ultimately injured by it; and if you have not some reasonable grounds for giving medicine, you have no right to run the risk of doing harm by its continued exhibition. It is much more wise, as well as much more honest, when you do not know what to do, to do nothing, and advise your patient to wait and take the chance of the pain subsiding of itself, as, in fact, it does in a great many instances."

It is my intention (with the kind permission of the Editor) to adduce further arguments (in a future communication) in support of the unity of the nervous system, and to prove, by reference to the actual phenomena of insanity and other nervous disorders, the folly and mischief of acting on the supposition that any one of the nervous—cerebral, spinal, or ganglionic—centres has an action wholly independent of the rest, or is governed by laws inapplicable or inappropriate to the whole.

Belper, South Derbyshire, April 1850.

MEDICAL GAZETTE.

FRIDAY, JULY 19, 1850.

THE facility with which the Plea of Insanity has been received in many criminal cases of late years, has naturally led to a closer examination of the legal and medical grounds upon which a person charged with an offence should be held irresponsible for his act. The case of a person named PATE, recently tried at the Old Bailey for an assault on the Queen, was well calculated to bring this question to a close issue. It was distinctly proved that the prisoner was odd and eccentric in his habits, and that on various occasions since 1842 he had been guilty of strange conduct in reference to mere trifles. His character, however, had undergone no marked change within a recent period: he had not been treated as an insane person, and had always managed his own affairs with average ability, and without rendering the interference of others necessary. Dr. Conolly, who had been consulted by his father respecting him about nine months since, admitted that Mr. Pate was labouring under no delusion, and that he knew the distinction between a right and a wrong action, but was subject to sudden impulses of passion. In committing the assault, Dr. Conolly considered that he had acted under some *strange sudden impulse, which he was quite unable to control*. Dr. Monro stated that the prisoner might have known what he was doing, and that the act of assaulting the Queen was very wrong, but he was satisfied the prisoner was of unsound mind.*

* This led to a somewhat indecent and uncalled-for reproof on the part of the judge. If there was any impropriety at all, it was in the counsel putting the question, and not on the part of the medical witness in answering it. The witness

We have it on good authority that the prisoner himself admitted the wrongfulness of the act, and that he committed the assault under some momentary impulse at the sight of her Majesty, which he could not resist.

The defence of such a case on the plea of insanity was beset with difficulties. Supposing it to be successful, the result would be incarceration for life in a Criminal Lunatic Asylum,—in itself a dreadful punishment for a person labouring under no delusion, and manifesting no insanity, in the common acceptance of the term, but, on the contrary, quite reasonable enough to appreciate the horrors of an imprisonment for life with lunatics. We cannot suppose that those who would sincerely urge such a defence, would propose to allow liberty to a man whose impulses were so sudden and uncontrollable that no one could be regarded as safe from his violence; and it would be ridiculous to assume, in a case of this kind, that there could be any certainty of cure. In short, had the learned counsel succeeded in such a defence, the safety of the public, which is far above any private considerations, would have absolutely demanded nothing short of imprisonment for life. There could have been no proof of cure after any period of confinement greater than that which was deducible from the prisoner's condition even the day before the assault;

merely said, in answer to the question, "he was satisfied the prisoner was of unsound mind." Would the learned judge have wished him to remain silent, or to have returned an answer conflicting with the evidence which he had previously given? The witness, after having replied to the question, was rather uncivilly told by Mr. Baron Alderson not to take upon himself the functions of judge and jury. "While I am sitting upon the Bench, said the learned judge, I will not permit any medical witness to usurp the functions of both judge and the jury." Dr. Monro very properly replied—"he considered he had only answered the question that was put to him." The judge should have interrupted the counsel, who was, no doubt, well able to justify his conduct, and not have reproved a medical witness, who, from his position in Court, could not defend himself from an attack of this kind, happily very rare, issuing from the judicial Bench.

and it is clear that he was not then a proper object of confinement or restraint, or his friends would not have allowed him to be at large. Even Dr. Conolly, when consulted about him nine months previously, advised that nothing should be done at that time. It is clear, therefore, he then thought so lightly of his condition that he apprehended no evil, and it is only *after* the act that we find an opinion expressed that the prisoner was of unsound mind.

We come, therefore, to the conclusion that, but for the assault on Her Majesty, there would have been no imputation of insanity against Mr. Pate. The acts relied on as indicating this weak mental condition may be paralleled any day within the circle of any man's acquaintance. We could enumerate acts of a much more strange and apparently unreasonable kind, perpetrated by men with whom no one would either have dared or have had a legal right to interfere; and the simple question is, therefore,—Shall such persons escape punishment *because* they commit breaches of the law, or shall a *momentary impulse* be a sufficient plea to ward off punishment from an offender, when the only evidence of a want of power of control consists in a medical inference derived from the extraordinary nature of the act, and the statements of the prisoner who is to benefit by the admission of the plea? Supposing that Mr. Pate had assaulted a mechanic in the open street instead of Her Majesty,—if the defence set up were good it would have been equally valid in this case. It cannot be assumed that the impulse was irresistible *because* the assault was upon Her Majesty, and that it would have been resistible had it been perpetrated upon one of her subjects! Such a mode of reasoning would be absurd. Wanton and unprovoked assaults are daily committed in the streets by persons who *could*, perhaps, produce good evidence

of general eccentricity, if such a plea as an uncontrollable impulse were admissible; but, in spite of the motiveless character of these attacks, the offenders are properly punished, partly as a matter of retribution, and partly to prevent their example from being generally followed. The safety of society demands this; and the security of Her Majesty demands that she should be equally protected from the acts of individuals who, after having inflicted serious personal injury, may coolly plead that they could not avoid it: they had a sudden impulse to stab, to put out an eye, or to break a head, and they could not control themselves! The very object of law in a social state, is to teach a person not to give way to the impulses of savage life.

Mr. Cockburn, counsel for the prisoner, put it to the jury that "the act itself was that of an insane man." "it was motiveless, objectless." He asked—"What motive could there be for the commission of the offence?" Such a line of argument would either prove nothing, or it would prove too much. What motive that would satisfy Mr. Cockburn could any individual in the kingdom have for assaulting Her Majesty under any circumstances whatever? We say none. If, therefore, the view of the learned counsel be correct, and his reasoning in favour of the acquittal of Pate have the slightest force, an assault on the Queen, whatever might be the result, should be taken *ipso facto* as evidence of insanity. In Pate's case there was not even the pretence of a delusive motive existing in the prisoner's mind, or a want of knowledge of the wrongfulness of the act at the time of its perpetration; and yet because, as it must necessarily happen in an assault upon the Queen, there was no motive, it is contended there should be no conviction, and no punishment. The Sovereign of these realms is, therefore, to

have a smaller degree of protection thrown around her than the meanest of her subjects. The learned gentleman who used this argument is now Solicitor-General, and it would only be placing him in a fair position to have his argument turned against himself; and its validity tested, in the event of his being called upon to exercise his office on some future occasion for the protection of Her Majesty against a similar dastardly assault.

It is fortunate, however, that the law does not admit this fast and loose way of dealing with impulses,—i. e., of making them irresistible or not, according to the station of the person who is the victim of them.

Mr. BARON ALDERSON, in addressing the jury on the evidence, said—"In the first place, they must clearly understand that it was not because a man was insane that he was unpunishable; and he must say that upon this point there was generally a very *grievous delusion* in the minds of medical men. The only insanity which excused a man for his acts was that species of delusion which conduced to and drove a man to commit the act alleged against him. . . . They ought to have proof of a formed disease of the mind,—a disease existing before the act was committed, and which made the person accused, incapable of knowing at the time he did the act that it was a wrong act for him to do."

Such a statement of the law may be, medically speaking, open to some objection; but, while it is the law of the land, we are bound to obey it: and to us it appears to afford a better and stronger protection for life and liberty than the doctrine of "irresistible impulses," when nothing but eccentricity of character can be proved. It is to be regretted, however, that the summing-up was marred by the undignified and flippant statement that "A man might say that

he picked a pocket from some uncontrollable impulse, and in that case the law would have an uncontrollable impulse to punish him for it!" It is said that the Law is a silent judge, and the judge a speaking Law. We have here, however, a judicial joke more befitting the pages of PUNCH than the lips of an occupant of the judicial Bench.

We conclude our remarks by observing that we do not remember to have met with a case in which the plea of insanity was advanced upon weaker grounds than in this. Admitting Dr. Comolly and Dr. Monro to be correct in their opinion that the prisoner was of unsound mind, it is clear from the present state of the law that his unsoundness or weakness of mind had not reached that degree to render him irresponsible for offences committed against others. Mr. PARK was not so mentally unsound as to be unsusceptible of correction by punishment; and the verdict returned against him will, we think, have the good effect of preventing others in the same weak mental condition from committing an assault upon Her Majesty. If the moral powers of such persons are not sufficient to control their criminal impulses, the recollection that a similar act was punished by seven years' transportation, may suffice to restrain the arm thus wantonly raised against the Sovereign.

DIABETES RESULTING FROM AN OVERDOSE OF NITRATE OF POTASS. BY DR. CARDON.

A MAN swallowed about three ounces of nitre, by mistake for two ounces of sulphate of magnesia. The immediate effects were violent irritation of the intestinal mucous membrane, and profuse diuresis. The intestinal irritation subsided, and was followed by incessant desire to eat and drink, accompanied by urination to the extent of seven or eight pints during the night.—*Journal de Chimie Médicale*. COURSE OF LECTURES
ON
DISEASES OF THE HEART.

*Delivered at St. Vincent's Hospital during the
Session 1849-50.*

BY O'BRYEN BELLINGHAM, M.D.

Fellow of, and Member of the Court of Examiners
of, the Royal College of Surgeons in Ireland, and
one of the Medical Officers of the Hospital.

LECTURE VIII. (Concluded).

EXAMINATION OF THE HEART IN DISEASE,
CONTINUED.

*Fremissement cataire, or purring tremor—
Circumstances under which fremissement
cataire is felt—Cause of fremissement
cataire—Signs furnished by percussion—
Alterations in the extent and degree of the
heart's superficial dulness—Conclusions
respecting percussion of the præcordial
region.*

THE cause of jugular pulsation was first satisfactorily explained by MM. Bertin and Bouillaud—viz., that it depends upon regurgitation into the great veins during the contraction of the right ventricle; and this theory of its cause has been almost universally adopted. Dr. Hope, however, supposed that it might have its cause in the recoil of the tricuspid valve upon the blood, when the hypertrophied ventricle contracted with increased force, and that the column of blood descending into the ventricle would be repelled with sufficient force to propagate its impulse as far back as the jugular veins. From the explanation which has been given of the manner in which the curtains of the auriculo-ventricular valves close their respective orifices, it would appear that jugular pulsation could scarcely be produced in that way. Why regurgitation is permitted at the tricuspid orifice so frequently, as well as the exact manner in which it occurs, have been already alluded to in treating of the "safety-valve function of the tricuspid valve."

FRÉMISSERMENT CATAIRE, OR PURRING
TREMER.

Another sign which is recognised only by the application of the hand to the parietes of the chest is the "fremissement cataire" of Laennec, the "purring tremor" of English writers, the "frottement fremissement ou vibratile" of Gendrin; named so by Laennec, from its resemblance to the peculiar sensation experienced if the hand is laid upon the back of a cat when the animal is making the peculiar purring sound which it does when pleased; and compared

by M. Bouillaud to the thrill felt on placing the hand upon the larynx of a person singing. It is a peculiar thrill, or vibratory sensation, very easily recognised, sometimes perceptible on very slight pressure upon the part, sometimes requiring a stronger pressure in order to be felt, and communicated equally by the large arteries as by the heart.

This phenomenon had been recognised as a sign of cardiac disease previous to the discovery of auscultation. Corvisart, speaking of the symptoms of disease of the left auriculo-ventricular orifice, observes—"Among the symptoms of this affection there is a peculiar confused sensation, difficult to describe, felt by the hand applied to the præcordial region." He supposed it to indicate a contracted state of the mitral orifice, causing an impediment to the passage of the blood from the left auricle into the left ventricle. Burns evidently alludes to this phenomenon when he speaks of a "jarring motion accompanying the pulsation of the heart;" and, as he noticed it in several cases where, on a post-mortem examination, the opposed surfaces of the pericardium were found to be adherent, he attributed it to this lesion, causing an impediment to the free action of the heart.

Fremissement cataire is not limited to the heart, but is perceptible also in the large arteries, and in aneurism, particularly in varicose aneurism, in which it is often better marked than in the heart. It is felt over the large arteries when the lining membrane of these vessels is extensively diseased, as well as in cases where no morbid alteration of the parts exists; and its cause, or the mechanism by which it is produced, do not seem to have ever been fully explained. Laennec* observes—"It would seem that the immediate cause of a phenomenon so marked as fremissement cataire would be easily discovered. I confess, however, that, notwithstanding the pains which I have taken in this respect, I have not been able to find any satisfactory reason." "It appears to me (he adds) extremely probable that it is owing to some peculiar modification of innervation." M. Bouillaud,† in the second edition of his work on the heart, expresses himself in somewhat similar terms:—"What are the other causes capable of producing this phenomenon (he observes) I am ignorant. It appears to me that there is a certain condition of the blood, as well as of the parietes of the heart and arteries, which favours its production. But in spite of the assiduous researches to which I have devoted myself on the subject, I have not yet been able to determine properly all these conditions."

* Auscultation Médiate, tom. ii.

† Traité des Maladies du Cœur, tom. i.

Circumstances under which fremitus cataire is felt.—In every instance in which fremitus cataire is felt, a murmur of some kind is audible on auscultation, which is frequently blowing, and sometimes rough or harsh. It is obvious, therefore, that the cause which produces the latter is connected with the cause which gives rise to the former; but, as fremitus cataire is not felt in every case in which an abnormal sound is heard, it is obvious that there must be something superadded when the latter is felt to allow of this peculiar sensation being communicated to the hand.

The morbid condition of the heart in which this phenomenon is most generally perceptible is where the left auriculo-ventricular valve permits regurgitation, and the ventricle is at the same time hypertrophied. The morbid conditions in which it is felt in the arteries are where the aortic valves permit free regurgitation, or where the arch of the aorta is dilated, its lining membrane rough and irregular from adventitious deposit, and the large vessels which come off from its arch are likewise dilated; where an aneurismal sac springs from a large artery, where a free communication exists between a vein and artery, as in varicose aneurism; or, finally, where the blood is altered, its viscosity diminished, its watery parts increased, and the vessels are in an unfilled state.

Two or more of the foregoing states may be combined together, by which the thrill will be increased. Thus dilatation of the arch of the aorta may be combined with disease of its lining membrane, and both may be combined with a state of the aortic valves permitting regurgitation; or dilatation of the large arteries, or regurgitant disease of the valves of the heart, may be combined with a state of anæmia and alteration of the blood.

Cause of fremitus cataire.—In every case in which fremitus cataire is felt, whether in the heart, or in the arteries, or in aneurism, the cavity or the vessel is in an unfilled state. Thus in the heart it becomes perceptible when the mitral valve permits regurgitation; in the large arteries, when the aortic valves are patent, when the arteries themselves are dilated, when an aneurism exists, or when a communication exists between a vein and artery. In several of the foregoing cases, regurgitation of the blood occurs; this presupposes an unfilled state of the vessel or cavity: it could not occur if they were distended. Now I consider this unfilled state of the vessels combined with a certain amount of force and velocity of the current of blood to be the immediate cause of this phenomenon: the thrill or vibration communicated to the hand being more marked when

the lining membrane of the part is rough or irregular from disease.

For instance, we can produce a fremitus at any time in a large artery in a healthy subject by making pressure upon it; the thrill is not felt at the point upon which the pressure is made, nor between it and the heart, but at the distal side of the point of pressure, and where the vessel must necessarily be in an unfilled state: a murmur is heard at the point compressed, and both cease as soon as the pressure is removed. We know, too, that a thrill, identical with fremitus cataire, is felt in cases where the heart and arteries are perfectly healthy, but where the vessels are in an unfilled state, as in anæmia, depending upon hæmorrhage or other causes.

A certain amount of force and velocity of the current of blood appears to be likewise necessary to its full development; because we find that this phenomenon sometimes diminishes or even disappears in diseased states of the heart, when the action of the organ becomes tranquil, and that it reappears again when the heart's action is excited by exercise. It disappears likewise when the action of the heart becomes feeble, and ceases altogether in the last stage of valvular disease when the circulation through the heart is much impeded.

The jarring pulse in the radial artery, with which we are familiar in cases of patency of the aortic valves, appears to be nothing more than the fremitus cataire felt in an artery of small calibre. The thrill communicated to the finger is characteristic of an unfilled state of the arteries, and becomes perceptible whenever the semilunar valves of the aorta imperfectly close the orifice, or when regurgitation occurs into the aorta from the large arteries which come off from its arch. The same character of the pulse is observed in cases where profuse hæmorrhage has occurred; and in a less marked degree in cases of anæmia from other causes.

Fremissement cataire may or may not be a sign of organic disease; in the majority of cases it is: thus, whenever it is felt in the præcordial region, accompanies the ventricular systole, and is well marked, it indicates valvular disease; and the form of valvular disease which will be found under such circumstances is a state of the mitral valve or orifice permitting regurgitation. In the large arteries, on the other hand, a fremitus may be felt, although no organic disease of the vessel exists. In some instances this phenomenon is perceptible when the hand is laid gently upon the parietes: in others stronger pressure is required in order to develop it. Thus in varicose aneurism, the result of a wound of an artery and vein, a thrill is communi-

cated to the finger on the slightest touch; while in cases of anæmia some pressure upon the artery is often required in order to make it evident.

A peculiar thrill or vibration is occasionally perceptible in the region of the heart, that must not be confounded with the phenomenon just described, and which arises from the direct friction of two rough surfaces during the motions of the heart: here it depends upon the friction between the opposed layers of the pericardium, which are roughened in consequence of the deposition of lymph upon them; the thrill has a different character from that of fremitus cataire, and is felt at a different part of the præcordial region. A somewhat similar feel is occasionally experienced when the hand is laid upon the side in cases of pleuritis or pleuro-pneumonia with false membranes; in bronchitis, likewise, when the sonorous râle is loud, a sensible vibration is sometimes communicated to the hand: in the latter cases, however, it accompanies the respiratory movements, not the heart's action.

SIGNS FURNISHED BY PERCUSSION.

The præcordial region includes the whole of that portion of the chest beneath which the heart is situated; and, in a healthy subject with a well-formed chest, the extent of surface in this region which yields a dull sound on percussion is limited. We have seen that the lungs are in contact with the greater portion of the anterior surface of the thorax, and, of course, wherever they are, the sound elicited by percussion will be clear. Where the anterior margin of the opposite lungs separates from one another, the anterior surface of the heart comes in contact with the thoracic walls, being only separated by the pericardium and cellular tissue.

The portion of the heart uncovered by lung is very small, seldom exceeding two inches in any direction: it has a triangular shape—the base below, the apex above; it consists of a portion of the apex of the right ventricle, and of part of the left ventricle near its apex, and is seated on a plane below the nipple and the fourth left rib: its base is on a line with the cartilage of the sixth left rib; its apex is at the point where the margins of the opposite lungs begin to separate from one another; its right boundary (which is constituted by the thin edge of the right lung) is nearly a vertical line through the centre of the sternum; its left boundary (which is constituted by the thin margin of the left lung) is an oblique line through the cartilages of the fifth and sixth left ribs.

This, then, is the only portion of the heart which in the healthy subject is in contact with the parietes of the chest, and

it is the only portion of the præcordial region which yields what can be termed a dull sound on percussion. It is not, however, quite correct to term this a dull sound: it is less dull than that yielded by the hepatic region: the liver being a solid organ, and the heart hollow, the sound elicited by percussion over the former is more dull than over the latter. Indeed, as Dr. Latham* observes, "percussion here conveys to the ear a sense rather of less resonance than of positive dullness." "If the percussion used be but of moderate force, you must listen attentively to make sure that the resonance is really less here than elsewhere. It is only when the percussion used is of a force somewhat painful to the patient, that the ear begins to acknowledge a positive dullness." On strong percussion, likewise, a difference in the sound can be detected where the thin margin of the lungs covers the heart. The sound here is intermediate between the clear sound heard on percussion over the lungs, and that yielded by the part of the præcordial region where the heart is in contact with the parietes of the chest. We can thus, as M. Piorry remarks, trace the vertical and transverse diameters of the heart, and we can measure its size from above downwards, and from side to side. The extent of the surface of the heart which is naturally in contact with the parietes of the chest is diminished somewhat, it must be recollected, in the supine posture; still more by taking a full inspiration. It is increased by leaning forward, and still more by a forced expiration.

In employing percussion in cases of disease, we may commence the examination of the præcordial region either above, below, or laterally; we may trace the sounds yielded by the lungs above and upon each side to this region; or, commencing below, we may trace the sounds from the region of the stomach, and of the left lobe of the liver, upwards. The mode of manipulation recommended by Dr. Hope† is "to lay one finger over the decidedly dull part, and another over the slightly resonant edge of the lung, when, by striking the two fingers alternately, the arched line along which the organ lies in contact with the walls may be traced with surprising accuracy, unless the subject be remarkable for obesity, which obscures the resonance." "In females, the mammae may be pushed upwards, which generally leaves the dull portion sufficiently accessible."

Alterations in the extent and degree of the heart's superficial dullness.—The extent of surface in the præcordial region which yields a duller sound than natural on per-

* Lectures on Diseases of the Heart, vol. i.
† Treatise on Diseases of the Heart, 4th edit.

cussion is seldom diminished, owing to diseased states of the heart; but it is very often enlarged, while the degree of dullness is not unfrequently at the same time increased. The space will be diminished if the heart is congenitally smaller than natural, or if the lungs are largely developed; and it will disappear if the anterior margin of both lungs is emphysematous, and their edges meet in front of the organ. But, as the heart is generally somewhat enlarged under the latter circumstances, a portion of its anterior surface will still come in contact with the parietes, but the space which yields a dull sound will be on a plane somewhat lower than natural.

The region of the heart's superficial dullness will be increased whenever the heart is enlarged, or whenever fluid to any amount is effused into the sac of the pericardium; in the latter case the degree of dullness will be likewise much more marked. Thus, if the walls of the ventricles are hypertrophied, or if their cavities are dilated, a dull sound will be elicited by percussion over a wider surface; and the extent of this surface will be in some degree a measure of the increased size which the organ has attained: the enlarged heart pushing aside the lungs, and a larger portion of it coming in contact with the parietes in the præcordial region. When the two foregoing conditions are combined, the heart attains the largest size that it is capable of, and the præcordial region may yield a dull sound over a square surface of from four to six inches, in place of two. When the hypertrophy predominates over the dilatation, the space which yields a dull sound is greatest from above downwards; when dilatation predominates over the hypertrophy, the region in which a dull sound is yielded is greatest transversely. In pericarditic effusion, likewise, a large surface in the præcordial region yields a dull sound, while the degree of dullness is much more pronounced, and the amount of fluid effused may be pretty accurately measured by the extent of the dullness on percussion.

When a dull sound is elicited by percussion over an extensive surface in the præcordial region, the situation in which it is most marked, and the amount or degree of dullness, will be a guide as to its cause. When it depends upon enlargement of the heart, the site of the dullness is lower down, and more to the left side, than when it depends upon liquid effused into the sac of the pericardium. As the pericardial sac extends upwards to a level with the articulation of the second rib on the left side with the sternum, and sometimes, as I have found to be the case, as high as the first rib, if a large amount of fluid is contained in this sac a dull sound will be elicited by percussion as high as this point;

while the degree of dullness on percussion over a fluid is always much more marked than over the heart itself. It is said that hypertrophy may be distinguished from simple dilatation of the ventricles by the degree of resistance to the fingers employed in percussion being greater in the former than the latter; but there are other and better signs by which these conditions of the heart may be distinguished.

The results furnished by percussion are, however, sometimes doubtful; for instance, when the margins of the lungs are emphysematous, and approach each other in the præcordial region, a clear, instead of a dull sound will be yielded in the natural situation of the heart's superficial dullness. When the lungs are solidified, either as the result of pneumonia or of tubercular infiltration, or from any other cause, a dull sound will be yielded upon each side of the heart over a considerable surface. When the heart is displaced, owing to liquid effusion into either pleura, or to some morbid growth in the cavity of the thorax, the region of the heart's superficial dullness will be altered.

Conclusions respecting percussion of the præcordial region.

1. The region of the heart's superficial dullness in the healthy adult subject does not exceed two inches in any direction. This space is on a plane below the nipple and the fourth left rib; its centre about the middle of the cartilage of the fifth left rib.

2. The sound elicited by percussion here is not absolutely dull unless pretty strong percussion be used.

3. The region of the heart's superficial dullness may be diminished, or it may be increased, or the degree of dullness may become more marked, owing to disease. It is much more frequently increased than diminished.

4. It will be diminished if the heart is naturally small, or the lungs are large and overlap the organ; and it may disappear if the anterior margin of both lungs is emphysematous.

5. It will be increased whenever the ventricles are hypertrophied, or their cavities are dilated, or when fluid is contained in the pericardial sac.

6. The seat of the diminished resonance always extends higher up, and is more extensive, as well from above downwards as laterally, when much fluid is contained in the sac of the pericardium, than when hypertrophy or dilatation of the heart exists.

7. The degree of dullness is always much more pronounced when fluid is contained in the sac of the pericardium than when the heart is enlarged.

Rebiews.

The Three Kinds of Cod-liver Oil, comparatively considered with reference to their Chemical and Therapeutic Properties. By L. J. DE JONGH, M.D., of the Hague. Translated from the German, with an Appendix and Cases, by EDWARD OBBY, M.D. 8vo. pp. 176. London: Taylor and Walton.

Cod-liver Oil: its Uses, Mode of Administration, &c. &c. Compiled from the best and latest Authorities, British and Foreign, by JOHN RAYNER. Pamphlet, 8vo. pp. 16. London: Churchill.

THAT cod-liver oil has maintained its position as a therapeutic agent of some value, notwithstanding its injudicious and indiscriminate laudation, by many who have spared themselves the pains of investigating its properties, is proof that it has some real therapeutic action. If, however, some may still think that it needs extraneous support, it may be found in the "First Medical Report of the Hospital for Consumption," which we have already noticed in a leading article (Jan. 14th).

We, however, again extract the following paragraph from this Report, as affording a sufficient reason for giving our readers an abstract of the works before us. The medical officers of that institution, Drs. Hamilton Roe, Theophilus Thompson, George Cursham, Richard P. Cotton, Richard Quain, and John Bowie, thus express themselves in reference to the medicinal properties of cod-liver oil:—

"From these facts, and a more extended experience since the period at which this report terminates, no other conclusion can be drawn than that cod-liver oil possesses the property of controlling the symptoms of pulmonary consumption, if not of arresting the disease, to a greater extent than any other agent hitherto tried" (p. 41).

Regarding this statement, then, as the first authoritative document relative to the therapeutic qualities of cod-liver oil, we take this opportunity of bringing the subject under our readers' notice.

The first section of Dr. De Jongh's treatise contains the source, method of

obtaining, and physical properties of cod-liver oil.

"Oleum Jecoris Aselli sive Jecinoris Aselli, Olerum Morrhua, Levertraan, Huile de Morue, Cod Oil, Olio di Baccala," are its various synonyms.

This oil is obtained from the livers of several species of *Gadus*, a genus of fish of the order Thoracici, family Malacopterygii. They are found in the Northern Atlantic, Levant, and Mediterranean Seas. There are six different species of *Gadus* which are found in the northern seas, and are taken on the Irish, Scotch, Norwegian, French, and American coasts. But it is uncertain from which species the oil is procured: it is even said that the fishermen themselves are not able to discriminate between them. In fact, it is procured from the several species indiscriminately.

Opinions vary also as to the method of obtaining the oil. Dr. De Jongh had instituted inquiries on this point. We quote the following from the letter of one of his correspondents:—

"In commerce there are three kinds of liver oil,—namely, from the dorse, seij-fish, and the pollack. The liver oil from the dorse, which is most noted, is obtained in the following manner:—The livers of 40 to 80 cwt. of stockfish are thrown into tubs, and are allowed to remain there until they become putrescent, when the oil runs off of itself: this, when skimmed, is the pale oil. What remains in the tubs is boiled in iron kettles (from sixteen to twenty hours) until it becomes of a dark brown colour, and is quite clear: this is the brown oil, which is strained, and the residuum in the kettles is used for manure" (p. 8).

The same method is pursued with regard to the livers of the other kinds. The oil differs in quality. The "light brown oil" is obtained from the livers of the seij-fish and the pollack. Its colour is caused by its being left a long time on the livers before it is poured off.

As one of the chief objects of this work was to investigate the chemical properties of cod-liver oil, so a greater portion thereof is occupied with the very full details of the analyses of the various kinds of oil, and of their organic and inorganic constituents. Of these investigations, extending over more than fifty pages, it would be impossible for us, within our limits, to give a sufficiently clear abstract. We must therefore content ourselves with extracting the author's summary.

"One hundred parts of cod-liver oil contain :—

	Brown.	Light brown.	Pale.
Oleic acid with brown substance (gaduine and two peculiar bodies)	69.78500	71.75700	74.03300
Margaric acid	16.14500	15.42100	11.75700
Glycerine	9.71100	9.07300	10.17700
Butyric acid	0.15875	—	0.07436
Acetic acid	0.12508	—	0.04571
Fellic and cholic acids, with some oleine, margarine, and bilifulvin	0.29900	0.06200	0.04300
Bilifulvin and bilifellinic acid, and two peculiar substances	0.87600	0.44500	0.26800
A peculiar substance soluble in alcohol	0.03800	0.01300	0.00600
A peculiar substance insoluble in water, alcohol, and ether	0.00500	0.00200	0.00100
Iodine	0.02950	0.04060	0.03740
Chlorine, with some bromine	0.08480	0.15880	0.14880
Phosphoric acid	0.05365	0.07890	0.09135
Sulphuric acid	0.01000	0.08595	0.07100
Phosphorus	0.00754	0.01136	0.02125
Lime	0.08170	0.16780	0.15150
Magnesia	0.00380	0.01230	0.00880
Soda	0.01790	0.06810	0.05540
Iron	a trace	—	—
Loss	2.56900	2.60819	3.00943
	100.00000	100.00000	100.00000

How far some of these "constituents" may be the result of the analytical processes, or obtained from the utensils employed, we presume not to judge; but we think it probable that some in this long list may have their origin in one or the other of these sources.

The author enumerates the various diseases in which cod-liver oil has been found serviceable. These are rheumatism, gout (both chronic and acute), scrofula, glandular swellings, scrofulous ulcers, chronic exanthemata, strumous ophthalmia, atrophy of children, rickets, mollities ossium, caries, white swellings, phthisis (in reference to the latter disease, the author styles this oil "the grand restorer of health"), otorrhœa, tumors of various kinds, paralysis, and some other chronic and cachectic conditions.

The author had investigated, in three series of cases, the comparative merits of the three kinds of oil, the inferences from which we here subjoin :—

"The three kinds agree so, that all the patients which were treated with cod-liver oil were cured, there being, however, a marked difference with regard to the time in which the cures were accomplished; evidently showing that there is a decided superiority in the efficacy of one kind over the others."

That this variation in the period of

the cure is not unimportant is shown by the author in a table which he has had drawn up for the purpose. From this table it appears that the cures by the brown kind were accomplished in half the time that was required by the light brown or the pale oil.

Although it will be seen, in the table given above, that the chemical composition of the oils varies, it would be extremely difficult to point out that feature in its chemical composition to which the greater efficacy of the brown oil can be attributed. It would, in fact, be equally difficult to indicate the chemical constituents of any or all varieties of the oil to which its general therapeutic properties can be assigned. Dr. De Jongh has the merit of having discovered a new body, which he names *gaduine*, in his analysis. It remains to be seen, from comparative analyses and experiments, how far this substance may perform an important part as a remedial agent, and whether it be peculiar to cod-liver, or to any particular class of oils. Dr. Carey, to whom the profession is indebted for his very excellent translation of this work, adds a few cases and remarks in illustration of the alleged therapeutic virtues of cod-liver oil.

Mr. Rayner's pamphlet is simply a notice of the therapeutic value of cod-

liver oil, the diseases in which it has been employed, and the authorities by whom it has been recommended.

In conclusion, we return to a brief consideration of the statement already quoted from the Medical Report of the officers of the Hospital for Consumption.

The curative agency of cod-liver oil is therein so distinctly affirmed, that, in bringing that drug under consideration, we could not omit some notice of a statement so pertinent, so authoritative, and so likely to influence practice.

We could have wished that the out-patients to whom cod-liver oil was administered had been distinguished from the in-patients; for it must not be overlooked that the nature of the patient's avocation, the degree of exposure to air, his general circumstances, &c., greatly influence the result of any plan of treatment. Such a distinction would also have thrown some light upon the degree of influence exerted upon the progress of phthisis by confinement in the wards of a hospital.

From our perusal of the work of Dr. DeJongh, and our personal acquaintance with the results of the employment of cod-liver oil, it remains still doubtful how far the apparent remedial benefit may not be attributable to its nutritious properties simply. Chemical analysis does not indicate the presence of any active principle in sufficient quantity to effect any therapeutic action, except upon untenable homœopathic doctrines; and a sufficiently extensive series of comparisons with the effects of other animal oils is wanting, to prove the exclusive possession of a specific virtue by the cod-liver oil.

The Report of the Hospital for Consumption shows an increase in the weight of the persons taking this oil, in one instance to the amount of forty-one pounds in sixteen weeks. But it must not be concluded that an equal improvement of the phthisical symptoms takes place *pari passu* with the increase of weight, although it is stated that the decrease of weight and aggravation of symptoms were generally coincident. Professor Paget* has drawn the attention of the profession to the fact that atrophy of all the most important structures may be progressing concurrently with a vast accumulation of adipose

tissue—that, indeed, obesity is but a form of atrophy.

From attentive consideration, therefore, of the facts thus brought before us, and by the aid of our own experience of the action of this remedy, we conclude:—

1. That cod-liver oil is a real therapeutic agent of some value in cachectic diseases.
2. That its value as a remedy has not yet been determined by sufficiently extended observations.
3. That the therapeutic action of cod-liver oil is manifested more especially in its influence on the nutritive functions.
4. That it is not yet determined whether this therapeutic action be peculiar to the elements of which cod-liver oil is constituted, or whether it be common to several varieties of animal oils.

Proceedings of Societies.

ACADEMY OF MEDICINE, PARIS.

July 9, 1850.

Coexistence of Sweating Sickness and Cholera.

DR. BUCQUOY, "*médecin des épidémies*" of the district of Peronne, stated the following to be the relations that he had observed to obtain between these two diseases:—

1. That where the sweating sickness was most severe, the cholera did not appear; and conversely.
2. That if the two appeared simultaneously in any district, the cholera was first to cease.
3. That individuals who had suffered a regular attack of sweating sickness were thereby protected from cholera.
4. That when the two diseases coexisted in a district, the sweating sickness was milder than when it occurred alone.

* * The sweating sickness (Malwah), as met with in India, appears to be closely allied to the worst forms of cholera, and to bear a close relation to malignant congestive fever. Its name, Malwah, is taken from a district in India.—*Dunglison's Medical Lexicon.*

The Intellectual Powers of Deaf-mutes.

M. GERDY read a critical examination of the opinions of Itard on the moral and intellectual powers of deaf-mutes, by M. FERDINAND BERTHIER, himself a deaf-

mute, President of the Central Society of Deaf-Mutes, and Dean of the Professors at the National Institute of Deaf-Mutes, Paris. M. Berthier considered that Itard had incorrectly and unjustly estimated the endowments of deaf-mutes, and proceeded to examine the several points of Itard's judgments.

M. Itard had stated that, being cut off from conversation, the deaf-mute is a solitary being in society, incapable of participating in the thoughts and emotions by which it is occupied or agitated: while, at the same time, he admitted that the deaf-mute has the advantage of the blind-born in the contemplation of nature, since he can include in a single glance of the eye more wonders than the blind person can imagine in a life-time. M. Berthier asserts that, by the aid of gesticulatory language, and by their extraordinary powers of mimicry, deaf-mutes are as capable of perfect instruction as those who have the use of oral language. That, although deprived of hearing, deaf-mutes are alive to all the events of social life. That numerous examples prove them to be capable of the highest intellectual exertions, of deeds of courage, of sensibility, and of patriotism; and susceptible of love, affection, pity, ambition, glory,—on all which points Itard had declared that by their physical condition they were inevitably incapable.

July 16, 1850.

'On Turning in cases of Deformed Pelvis.'

DR. CHAILLY HONORÉ read a memoir, the object of which was the examination of the question, whether it is advisable to substitute version for the use of the forceps in cases where the head presents, the antero-posterior diameter of the pelvis measuring less than two inches and a half. The author discussed Dr. Simpson's proposal to turn in these cases, and concluded that it is in opposition to sound practice, and to all the experience of the greatest authorities in obstetric science. The proceeding, Dr. Chailly-Honoré observed, deprives both mother and infant of every other obstetrical aid, exposes the infant to certain death, and the mother to the risk of serious injury.

Fracture of the Temporal Bone.

M. DEONARD read an essay, in which he observed that fracture of this bone is not always attended with hæmorrhage; that, when the latter occurs, its source is frequently laceration of the carotid artery in the carotid canal; that deafness is a certain sign of this fracture; and, lastly, that it is not always a fatal occurrence.

SURGICAL SOCIETY OF PARIS.

July 10, 1850.

PRESIDENT, M. DANYAU.

Reduction of long-standing Dislocation.

M. FORGET related the particulars of a case in which the reduction of a dislocation of the shoulder-joint, of three months' standing, was accomplished by Lisfranc: the patient died suddenly an hour after the operation. The only cause of death which could be discovered was congestion of the brain.

MM. LENOIR and LABREY related instances of injury to the brachial plexus of nerves, from attempts at reducing long-standing dislocations.

M. HUGUIER stated that a patient to whom chloroform had been administered during the operation of reducing a dislocation of the hip-joint, having died a short time afterwards, from another cause, it was found, at the autopsy, that the dislocation had not been reduced, as was supposed, but that the bone had been fractured.

Some further discussion took place, in which the majority of the members expressed their disapprobation of long-continued attempts to reduce old dislocations. M. Forget expressed himself strongly, on the dangers attending the use of chloroform in such cases.

ACADEMY OF SCIENCES, PARIS.

July 15, 1850.

Electrical Phenomena produced by voluntary muscular contraction.

M. POUILLET read a report on a memoir on this subject, by M. BOIS-RAYMOND, of Berlin. The existence of an electrical current at the time of voluntary contraction of the muscles was admitted, and the following opinion on its cause given, by the commission, composed of MM. Magendie, Becquerel, Rayer, Despretz, and Pouillet:—

That the cause of the current is unknown; it is probable that it does not result from any chemical action. It is not demonstrated that it results from any internal chemical action. According as this problem shall receive an affirmative or negative solution, the ulterior consequences will assume a different character.

Analysis of the Blood of Animals after acute suffering.

M. CLEMENT showed that the blood of animals undergoes a modification in its composition, from acute suffering, and that

under these circumstances the activity of the organic functions is greatly increased. The results stated by M. Clément, from his researches, are—That the water and colouring matter of the blood are augmented in proportion to the decrease of the albumen and fibrin; that the albumen is decreased in the proportion of about a seven-thousandth, and of the fibrin in that of a three-thousandth. That under these conditions, chemical changes are effected rapidly on the soft tissues of the frame, to restore the composition of the blood.

Radical Cure of Inguinal Hernia.

M. VALETTE described a proceeding which he had contrived for this purpose, and which consisted in the reflection of a portion of integument into the canal, the production of ulceration, and the ultimate union of the opposed surfaces by cicatrization. M. Valette had tried this proceeding in five cases, and promised to submit further results for the consideration of the Academy.

Hospital and Infirmary Reports.

ST. GEORGE'S HOSPITAL.

Cases reported by A. WHITE BARCLAY, M.D., Medical Registrar to St. George's Hospital.

THE accompanying cases are of interest, from the fact of the circumstances being so nearly similar, and from the cases occurring within a few days of each other. The remarkable feature presented by both cases is this, that permanent disease of the kidney may derive its origin from stricture of the urethra, and may prove fatal after the urethra has been restored to an almost normal state, and its immediate consequences of chronic cystitis or nephritis are to appearance entirely removed. The second case forms a commentary upon the first, showing the affection at an earlier stage, when neither the stricture nor the chronic inflammation had been entirely removed by treatment.

CASE I.—Henry Skinner, *stat.* 34, admitted into St. George's Hospital on 12th April, 1850, under the care of Dr. Page. This man, a carpenter by trade, was engaged in his business when suddenly attacked by hæmoptysis, bringing up about a quarter of a pint of blood at once, and the sputa continuing mixed with blood at his admission. He said he had suffered from cough during six weeks past, with

pain in the chest and thickish expectoration; and there was dulness on percussion under the left clavicle, imperfect expansion of the chest, especially on that side, and moist râles to be heard at the upper part of both lungs. He believed he had spit a little blood on a previous occasion, but was uncertain. He was ordered a purgative of calomel, to be followed by a senna draught, and a mixture every four hours, with sulphate of alumina, sulphate of magnesia, and dilute sulphuric acid; and, as there was some return of the hæmoptysis, he was cupped next day between the shoulders to eight ounces, with relief. The expectoration diminished, and the blood disappeared from the sputa; and he was looking better, but had a sallow and unhealthy aspect. He complained that his mouth felt parched from the alum in his mixture, which was discontinued.

On the morning of the 18th his tongue was dry and parched, and very coated. He had had slight epistaxis, and was beginning to be confused in mind; was in a nervous and excitable state, and a good deal inclined to sleep: the pulse was quick and rather sharp. The moist and crepitant râles were found to have extended considerably down the back of the left lung, and the breathing to be pretty natural on the right, but was much hurried. His whole appearance led to the suspicion of the existence of disease of the kidney; and, accordingly, on examining the urine it was found tolerably abundant, clear, acid, but containing a very notable amount of albumen. He continued in the same rambling confused state of mind till towards evening, when he became decidedly delirious, attempting to get out of bed two or three times, and in the last attempt falling on the floor in a fit. He was from that time quite unconscious, lying in a state of partial stupor, recognising no one, tossing about a good deal in bed; with contracted pupils, and sordes about the mouth, breathing heavily, and sighing. He passed no urine during that day, but gradually sunk into a state of coma, and died on the evening of the 20th.

Sectio cadav. 55 hours after death:—

Head.—Not examined.

Thorax.—The surface of left pleura smeared with recent lymph, with old partial adhesions at upper and back part. The posterior part of left apex much punctured from contraction of old vomicae, containing chalky matter about size of a hazelnut. Both lobes were partly solidified from recent lymph infiltrated in structure, were soft and friable, breaking down under finger, and sinking in water. The right lung was congested at the lower and back

parts, but otherwise healthy. Heart large, and loaded with fat, slightly hypertrophied in substance, and small patches of atheroma at root of aorta; valves healthy.

Abdomen and pelvis.—The pelvis and infundibula of both kidneys much dilated; secreting structure expanded into thin bags, about quarter inch in thickness, with pale and smooth surface. Ureters distended throughout to about size of little finger. Bladder distended, healthy. Urethra contracted at its bulbous portion to about two-thirds of its normal size; prostate healthy. Other organs presented nothing remarkable.

CASE II.—John Middleton, æt. 43, admitted on 17th April, 1850, into St. George's Hospital, under the care of Mr. Tatum, alleged to have suffered for some time past from stricture, and with the view of having the catheter passed. He presented a rather sallow and unhealthy aspect, so as to suggest to his surgeon the idea that the case might be one of suppression from disease of the kidney, rather than of retention produced by stricture. He was ordered a purgative at once, and a warm bath in the evening; and, having passed water without difficulty in the course of the night, an attempt was made to pass the catheter, which was opposed by spasmodic action, in consequence of which it was not repeated for some days, and he continued using the warm bath, and taking a mild sedative every night, with an occasional dose of castor oil. The catheter was again introduced on the 27th, and passed without difficulty. Nurse reported that he had a slight rigor in the night; and, observing his breathing somewhat stertorous, and his sleep heavy, she called the attention of the house-surgeon to the case, by whom Dr. Bence Jones was asked to see him. It now appeared that some peculiarity of manner had existed all along, but had become much more marked this morning; and, at the hour of visit, he started up when waked out of sleep, seemed confused and flurried, and could not give a very distinct account of his feelings. His pulse was full and bounding; tongue coated, and inclined to be dry; the bowels had acted freely; and, on examination of the chest, nothing was observed, with the exception of sonorous and moist râles at the lower and back parts of both lungs. The urine was desired to be saved for examination, and he was ordered to be cupped to ℥iv . on the loins, had a saline draught with antimonial wine every six hours, and a compound jalap powder next morning. A smaller quantity of blood than had been ordered was obtained by cupping; and becoming comatose in the evening, he was bled, from the arm in a full stream, during

which the pulse sensibly flagged; but after a short time he rallied, said he felt better, and continued comfortable through the night, relapsing into coma in the morning. Blisters were applied to the neck, the bleeding repeated, purgative enemata, &c., administered; but there was no return of consciousness, and he died on the evening of the 30th. The urine was found to be very highly albuminous, but containing no fibrinous casts or blood globules.

Sectio Cadav. 17 hours after death.

Cranium: The sinuses and large veins distended with dark blood. A considerable quantity of serous fluid in the cavity of the arachnoid, and also infiltrated into the subarachnoid areolar tissue, over the surface of the hemispheres, and at the base of the brain. Substance of the brain wet, puncta numerous and dark. Ventricles distended with clear serum.

Thorax.—Ten old adhesions in left pleura. Both lungs gorged with frothy serum: a few tubercles at the left apex. Heart normal: a few patches of atheroma in the aorta.

Abdomen and Pelvis.—Kidneys large, and much surrounded by fat. Pelves and infundibula greatly distended, expanding the substance of the kidneys, and forming pouches which dipped between the pyramids; found to be lined by mucous membrane, which was very vascular, and filled with a smooth creamy-looking pus. The substance of the kidney was much wasted, soft, pale; structure indistinct, and in many parts scarcely a quarter of an inch in thickness. In the cortical structure of the right kidney there were numerous cysts, and some small abscesses of the size of pins' heads, which seemed to be uriniferous tubes distended with pus. The investing membrane was rather adherent; surface pale, smooth, and marked by vascular stellæ, and a few cysts. The ureters were distended to the size of the little finger. Bladder distended; filled with urine mixed with pus; considerably hypertrophied, and mucous membrane very vascular.

The bulbous portion of the urethra presented considerable irregularity, and some degree of constriction, with chronic thickening, but admitting a No. 6 catheter. The other organs appeared to be healthy.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 18th July, 1850:—James Edward Tuxford, Boston, Lincolnshire—Joseph Bray Gilbertson, Preston, Lancashire.

FELLOWS' PRIZE REPORTS OF

CASES OCCURRING IN UNIVERSITY COLLEGE
HOSPITAL,

Summer Session 1845.

By C. H. F. ROUTH, M.D. Lond.

CHARLES LEE, æt. 30; admitted Tuesday,
June 24, 1845, under Dr. Williams.

CASE.—*Tubæ Mesenterica*—*Tubercle of
Lungs*—*Gastralgia*—*Perforation of the
Intestines*.

(The particulars obtained from the pa-
tient himself.)

Of moderate stature, spare conformation,
scrofulous temperament, fair complexion,
blue eyes, and red hair. For the last
twelve months he has been engaged as a
painter; for the previous sixteen years as
a confectioner. Had continued at work
up to six weeks since, when he failed in
business.

He has resided for the last three weeks
at No. 14, Duke Street, a very damp and
close house, especially so on the ground
floor, where he lived. In London all his
life. Formerly his food was usually good
of its kind; meat every day; seldom
greens. He very rarely took any supper;
when he did, it was only bread and cheese.
His habits are also temperate; he generally
takes Oj. of porter daily; very rarely spi-
rits. Has not been intoxicated for the last
eighteen months. Lately he has been in
the habit of drinking largely of tea and
coffee, and that not of the best kind. Has
not eaten any solids for the last fortnight;
has been very hard-worked; sleeps gene-
rally eight hours out of the twenty-four.
Disposition very cheerful.

Hereditary predisposition.—Father died,
æt. 50, from bursting a bloodvessel. His
mother died of paralysis. Has one brother,
who had colic eight years ago, but is
otherwise healthy. He is not aware that
any of his family have disease of the sto-
mach, are scrofulous, or consumptive.

Habitual state of health.—Has always
been generally healthy and strong, though
thin. Had small-pox when a child. Six
years ago he had an attack of dyspepsia,
accompanied with severe abdominal pain
and headache; he was also very sick, but
did not vomit. He was told it was dyspep-
sia, but there was no pain at the stomach
with it. He fell out of a window when
17 years old, upon his face, and it was said
he had injured his chest at the time; he
was, however, only laid up for a fortnight
after the injury. He had rheumatic oph-
thalmia nine months ago, but it was unac-

companied with other rheumatic symptoms
about the body. Has not been liable to
coughs; never had hæmoptysis.

Present attack.—In addition to night
sweats, which have annoyed him for the
last three months, he has felt much uneasi-
ness at the stomach, and a sensation as if
it was filled with water and going to burst;
but no actual pain. For the last six weeks
especially, all food taken internally has felt
heavy upon his stomach; but there has
been no nausea or vomiting with it, head-
ache, giddiness, or a bad taste in the
mouth. His bowels were also obstinately
costive, and there was occasionally severe
spasmodic pain, as if he had colic. These
symptoms would usually last about an
hour, and be relieved by a cup of warm tea
or cold porter. This sensation of fullness
or pain was only induced by the ingestion
of solids, not liquids, which produced no
inconvenience. He continued much in the
same state up to a fortnight since, when
fluids also began to affect him, and there
was pain in addition, generally more or less
intense, which even when his stomach was
empty would be produced by walking,
with this difference, that it would then
partake more of the character of soreness
than of actual spasm. Six days ago the
pain became so much worse, that he was
obliged to keep his bed, and avoid all exer-
cise. There was also much dyspnoea, with
a considerable amount of tympanitis, but
no palpitation at the heart. He was under
the care of a medical gentleman, who gave
him some medicines which opened his
bowels freely, but nothing more. He had
always been costive, frequently going a
week together without a motion. On this
occasion his bowels had not been opened
before for three or four days, and what
came away in consequence of the purgative
was of a very dark almost pitchy colour,
and very offensive. How long his motions
had been of this nature before, he had not
observed. He has lost a good deal of flesh
during the last three weeks. He was able
to walk to the hospital, though he suffered
much pain and dyspnoea in so doing.

Present state.—The colour of the skin
generally over the trunk is sallow; but
there is no eruption or increased cutaneous
sensibility. He is much emaciated. He
states he prefers a lateral decubitus, as
then his mouth remains moist! No rigors;
skin cool and moist. He is so weak he
can hardly stand, and walks with the
greatest difficulty. His feet do not swell
at night. Feels very languid and restless;
perspires a great deal during his sleep;
expression of countenance anxious; cheeks
very sallow, hollow, and sunken in; malar
bones very prominent; lips pale; eyesight
not affected; pupils naturally dilated;

small and hearing natural; there is no headache. He had slight occasional giddiness prior to his admission, but not now. Sleeps very badly on account of restlessness. Intellect clear.

Thoracic organs.—The chest measures 31 inches round on a line with the nipple; both halves 15½ inches; respiratory movements equally costal and diaphragmatic; ribs very prominent; respirations 20 in a minute. The vocal vibrations somewhat stronger on the right than on the left side beneath the clavicles; both sides resonant; if any thing the right is duller than the left, and the pitch on percussion higher. The expiration is *too loud* under both clavicles, especially on the right side. Behind, this difference is much more marked over the right supra-spinous fossa, where the respiration generally is weaker, but the expiration is louder, than that on the left side. There is a slight hacking cough in the morning, with some trifling mucous expectoration. The voice is decidedly hoarse. No palpitation or pain at the heart; sounds healthy. There is a slight regurgitation in the veins of the neck. Pulse 88, small and weak. There is no spinal tenderness or pain.

Abdominal organs.—There is slight tenderness over the region of the stomach, especially at the epigastrium, and to the right side; here, also, he feels pain. There is also, generally, a sensation of pain, and a feeling of weight in the stomach when he takes food, or *warm* drinks. The pain, but not the sensation of fullness, is relieved by cold drinks. This pain after eating lasts sometimes an hour, sometimes less. It does not come on immediately, but after ten minutes or so. When he drinks there is nausea, but no actual vomiting. This pain is increased by walking. The abdomen is rather prominent, irregular, and resisting; but no distinct tumor can be felt. Liver reaches as high as fifth rib, and projects three inches below the margin of the ribs; it is also somewhat tender on pressure. The abdomen is tympanitic in all its parts, but not tender; passes a good deal of flatus by the bowels; no motion to-day; urine free, but very high coloured.

The tongue is furred, dry, lobulated at the apex, and redder than natural; mouth generally dry and clammy. No appetite; much thirst. The teeth generally decayed, with a distinct white line around the margin of the gums. Many of the teeth are also loose.

Supposed exciting cause.—He imagines the first attack was brought on by an excessive indulgence in confectionery, eaten at all hours of the day. At this time he was unable to eat his ordinary meals. When a painter he lived very well, but lat-

terly but very indifferently,—his brother's wife being a bad manager, and serving liver, kidneys, and sheep's fry, which he did not like; so that he lived almost exclusively on vegetables.

Treatment.—Low diet. *R.* Hydrarg. Chlorid. gr. iv.; *Ext.* Conii, gr. vj. fiat pil. ij. hac nocte sumend. *Cras* mane sumat. *Ol.* Ricini, *ʒss.* *R.* Acid. Hydrocyan. Dil. *℥v.*; Soda; Sesquicarb. gr. x.; Aqua Menth., Mist. Camph. aa. *ʒss.* ter die s.

June 26th.—The bowels not having been relieved by the pills and oil, these were again repeated. To-day they have been open twice. There is *no pain* whatever after eating, though the epigastrium is still tender on pressure, and he feels occasionally sick; but there is no actual vomiting.—*Pt.* Mist. Rep. *Ol.* Ricini, *ʒj.*

27th.—His bowels were moved only once by the castor oil. He continues much in the same state, only that he experiences no difference on taking warm or cold drinks. There is no pain at the stomach.

28th.—He is not quite so well to-day; the stomach feels very full, as if he had drank a great quantity of water. There is some tenderness at the epigastrium; no sickness, but a bad taste in his mouth after eating; occasionally heartburn. To-day he seems to find that warm drinks again hurt him. Abdomen continues tympanitic, but nowhere tender, except over the hepatic region. Pulse 96, full. Tongue still dry, and very red at the apex. Bowels not open since yesterday. Sweated a good deal last night, and feels very weak, especially across the loins; was unable to sit up to take his breakfast by reason of this feeling of weakness.—*R.* statim sumat. *Ol.* Ricini, *ʒss.*, et repet. omni mane. Middle diet.

July 1st.—He has continued to sweat profusely every night since last report: last night, however, he thinks it was less than before. Feels very weak. He can only walk across the ward in a tottering manner. His feet, however, do not swell at night. The face looks perhaps fatter than it did when he came in, and has lost the hectic flush. There is no headache; but he complains of a good deal of dimness of sight, so that after reading ten or twelve lines in a book, his sight becomes so dimmed, he is obliged to put the book down. This symptom he never before noticed. Slept better last night; and to-day he feels rather drowsy. The hacking cough is rather less frequent than it was: no expectoration; pulse 96. The blue line at the margin of the gums still persists: teeth generally black and loose. No pain whatever over his stomach, nor tenderness, even on hard pressure. No feeling of weight or pain after eating; no nausea or bad taste in the

mouth. His appetite is better; and he very much relished a chop ordered for him yesterday. Bowels open: stools light-coloured. Abdomen still resonant and tympanitic.

3rd.—To-day he has no pain at the stomach. Last night, however, between 11 and 3, he suffered with a dull pain at the epigastrium, which finally disappeared on the expulsion of flatus. After his dinner to-day he felt again the sensation of fullness, though he ate but little, and less potatoes than usual: it did not last longer than half an hour. Tongue is clean.—*R. Fiat haust. c. Infus. Calumbæ loco aquæ.*

4th, 2 P.M.—When he took his tea last night, he had a return of the gastric pain, which lasted about two hours. The castor oil this morning began to affect him. After taking it he felt very sick and cold, and became covered with cold sweats: the gastric pain also recurred. These symptoms passed off in half an hour. This morning he was very hungry; but the food he took brought on the same kind of pain he was suffering from before his admission. He ate only half a chop this afternoon, and the same pain recurred, and has continued ever since. Bowels open.

5th.—There are no general pains, no anasarca, no headache or giddiness. Sleeps very indifferently. Feels very cold, sick, and faint, and is covered with cold sweats, after taking the castor oil; the pain at the stomach is also reproduced. The other medicines he takes do not affect him in the same manner. The abdomen is still large and tympanitic, more particularly in some parts; it seems too full, though no actual tumor can be detected. *Vocal fremitus is felt transmitted through the parietes of the abdomen.* There is some tenderness on pressure in both iliac fossæ, and slight fluctuation in the right iliac fossa; but it is so circumscribed and confined, and not moving on pressure, that most likely it is contained in the intestine. The patient being turned on his belly, there was some superficial tenderness over the loins. It was not tympanitic on the right side, and parts dull before did not alter on making him change his position a little. The most inferior and depending side was also quite tympanitic, whatever side he was laid upon. The abdominal tenderness seems to be more superficial than deep-seated. The kidneys and mesenteric glands cannot be felt from pressure in front. There is a sensation of fullness that now comes on after every meal immediately, and persists for two hours. It is, however, scarcely as severe as it has been.—*R. Fiat. haust. ut antea c. aqua loco Calumbæ; Omitte OL. R Ext. Colo-*

cynth Co.; Ext. Conii, aa. gr. v. fiat pil. o. n. s.

7th.—The pain in the stomach yesterday was very severe, aching continually, with little intermission. The part is tender and sore on pressure. To-day he is much the same. Perspired a good deal last night, but could not sleep. No headache, palpitation, or sickness. He has not been able to eat his chop the last two days, but he gets it made into broth, which he finds agrees better with him. To-day, after his breakfast, the gastric pain recurred rather sharp in character. The same thing occurred after his broth, but it lasted only fifteen or twenty minutes. Tongue is again morbidly red and dry. Pulse 104, very weak.

8th.—Chest expands well. On percussion, the right side continues to be duller than the left. The right end of the sternum appears to protrude more than left. The breath sound, as also the voice sound, is tubular beneath the right clavicle: much more natural under the left. Behind there is dulness in both interscapular spaces, and some pain on percussion over the left side. The right supra-spinous fossa is decidedly duller than the left, and the breath and voice sounds strongly tubular. It is slightly so in both interscapular fossæ, but especially the right. The tongue continues morbidly red, deprived of its epithelium, dry in front, with a slight fur posteriorly. The pain in the stomach is no better. Bowels open.—*Auge Acid. Hydrocyan. dil. ad ℥vjij.; Empl. Lyttæ epigastrio.*

10th.—He is rather better to-day. The blister rose well: and to-day the pain in the stomach is relieved, and no longer induced by taking food. The sensation, also, of faintness has disappeared. He does not sweat so much at night as he did, but he sleeps little, owing to the blister, which externally is very sore.—*R. Auge Acid. Hydrocyan. dil. ad ℥ix. sing. dos.; omne nocte habeat Ext. Hyoscyami, gr. v.*

11th.—He again perspired a good deal last night, and feels very weak in consequence to-day. His countenance is remarkably free from any appearance of anxiety, but looks very thin. Pupils much contracted. No headache or giddiness. The tongue is still morbidly red. The blue tint on the margin of the gums persists, but is less evident. Cough trifling, no expectoration. There is no pain, feeling of weight, or slightest uneasiness, in his stomach after eating. He still takes broth instead of the chop. Pulse 104, rather fuller than it was. The bowels were open four times last night, and once this morning, and the morning motion, which he saw, had the appearance of pitch.

12th.—To-day there are a good many white pellicles, aphthous-looking spots, on the roof of his mouth and tongue. The epithelium is wanting in some parts, which have, therefore, the appearance of being excavated. There are, also, a few follicles on the gums. His mouth is occasionally very dry, and he feels very thirsty. There is no abdominal or gastric pain after eating. Takes chiefly fluids. Bowels open three times last night. The physical signs of the lungs continue much the same. On the right side the respiration is tubular: on the left side the expiration is too loud, but there is a good deal of vesicular murmur below. He cannot sleep at night. —R Auge in Mist. Sodæ Sesquicarb. ad gr. xv.; Omni nocte sumat. Morphine Hydroch. gr. $\frac{1}{4}$ loco Hyocyami.

14th.—This morning when he got up his mouth was so sticky he could not articulate; but after drinking a little he was enabled to do so. He has felt very sick, but has not vomited. The face looks very thin. Cheeks hollow and sunken. The tongue continues morbidly red, here and there deprived of its epithelium, with a few aphthæ still. There are, however, none on the roof of the mouth. The gastric symptoms are equally improved. Bowels open to-day, not yesterday, but he has not noticed the colour of his motions. 3iv. of urine saved. Tested with nitric acid it gave at first a deep blue colour, passing into a red, and finally into a dirty brown colour. Hydrochloric acid produced no effect on the heated urine. Acid; sp. gr. 1027. R. Fiat. Haust. c. Decoct. Cinchona, 3j. loco aquæ.

15th.—He was rather delirious last night, which he attributes to the morphia. He is looking very thin. The expression of his countenance, however, is quite free from anxiety; indeed, rather expressive of great indifference. Abdomen generally tympanitic; but in the most depending points there is also slight dulness on superficial percussion, and slight fluctuation detectable. Bowels open.—R. Omitt. pil.

16th, 10 A.M.—The patient looks very pale and thin: his face covered with cold perspirations. Extremities cold. There is considerable tenderness on pressure over the abdomen. Last night, towards morning, he began to suffer much pain in the abdomen, and he had what he calls an immense motion in his bed, which relieved the pain. About six or seven o'clock, feeling again an inclination to go to stool, he got up, but while in the act of walking to the closet he suddenly felt very faint, and fell to the ground, by reason of passing a large quantity of blood per anum, which was sprinkled on the floor of the ward. The nurse says that what he passed in the

bed was pure blood, but that on the floor was blood mixed with fecal matters. Altogether she imagines he lost about Oiv. of blood. It was of a dark colour, somewhat pitchy-looking, but here and there with clots of more florid coloured blood. It was very offensive, and resembled in odour carcinomatous discharges. He is very thirsty. No appetite. He has eaten only a piece of cake, and taken a little brandy and water, which was given to him at the time. Neither gave him pain, or brought on the sensation of fullness at the stomach. Pulse 130, very weak and tremulous.—R. Omitt. Haust. R. Plumbi. Acet. gr. ij.: Pulvis Opii, gr. $\frac{1}{2}$; Ext. Humuli, gr. iij. fiat pil. 6tis horis sumend. Wine, 3vj.

3 P.M.—His extremities are a little warmer, and he feels stronger than he did this morning. Has had no motion since. Pulse rather fuller, 124. Skin moist. In other respects he feels much about the same as this morning.

17th, 10 A.M.—His face looks extremely pale this morning, and bedewed with cold perspirations. Cheeks more hollow and sunken than before. The countenance still expressive of great indifference, as before remarked, but he says he feels stronger. No headache, giddiness, or tinnitus aurium. His tongue morbidly red and dry, so that he articulates with difficulty. Pulse 128, rather fuller. Yesterday evening, between four and five, he had another motion, consisting almost entirely of blood. It was not so pitchy as before, and consisted more of clots. At seven he had another motion of the same kind, but it contained some fecal matter also—both equally offensive. He was very faint at the time, but recovered under the influence of wine. He is very thirsty, and takes his wine with avidity, and which he appears to swallow with greater ease than yesterday. No perspirations last night. Slept well. The nurse supposes he lost about O $\frac{1}{4}$ of blood.

3 P.M.—He says he feels very faint, but his extremities are warm. Face looks paler, more sunken, and generally thinner than it did this morning. His head is rather hot. Pulse 124, very weak and compressible. There is no tenderness of the stomach, but a little in the right iliac region. On pressing deeply over the pylorus the hand comes against some hard substance much nearer than the spine. It was not the liver, for although this extended one inch below the margin of the ribs the tumor was much deeper than it. Over the right iliac fossa there is a slight layer of fluid to be detected on pressure, communicating to the hand a distinct feeling of irregularity and gurgling. Has not had his bowels open since yesterday at seven o'clock. There is considerable hic-

cough at present, with some abdominal griping occasionally. The sensation of weight returned to-day after he took his tea. Has eaten nothing the last two days but a small piece of cake. He does not fancy his chop, but seems to think he would like fish. Respiration easy.—*R. Auge Plumb. Acetatis*, ad gr. iij. s. d.; *Cras mane habent Magnes. Sulph. ʒij.*; *Acid. Sulph. dil. ʒjxx.*; *Aque Menth. pip. ʒiss.* To have fish instead of the chop daily.

18th.—By mistake the medicine was given last night instead of this morning: it produced great pain for two hours, which was then relieved by a copious motion, full of scybala, but containing no blood. Afterwards they were again opened. The abdomen is not so full to-day as it was, but still much too much so to the feel. Aorta can be felt pulsating in it. Slight tenderness in the iliac fossa, as over the situation of the right kidney. No cough, but the breathing is a little quicker than natural. Pulse remains quick, 120, very jerking and compressible. Tongue very dry, so as both to interfere with deglutition and articulation. No increase of the aphthæ about the mouth. No pain in the stomach, headache, or giddiness.

19th.—Perspired a good deal last night, and felt this morning very weak and restless. The countenance is still remarkable for the expression of complete indifference it exhibits. He is very thin and pale. The organs of the senses do not appear to be at all affected. No headache or giddiness. He is slow in giving utterance to his ideas, but in other respects perfectly rational. Mouth continues very sticky and dry. There is a slight hacking cough, rather more frequent than it was before, but without expectoration. Sleeps very badly. Skin hot and dry. Extremities warm. He has had a good deal of pain and spasm in the stomach to-day, which is, however, not tender on pressure. No pain in iliac fossa to-day. No appetite, and has not been able to eat any thing to-day. Bowels not open to-day. Last night they were so once: the stools slightly tinged with blood, and very offensive. Urine, sp. gr. 1027. Nitric acid producing the same black and brown colour when a few drops are added, but which is taken up by the addition of a little more.

21st.—Yesterday he was very ill, and much purged, and whatever liquids he took brought on a motion. The first motion passed was somewhat bloody, containing a number of small clots about the size of small peas floating in it. The remainder were fecal, but all excessively offensive, the odour bearing great analogy to that of cancerous discharges. He did not faint,

but was very nearly doing so once or twice, but recovered after taking some wine. He was ordered—*Tinct. Opii, ʒiv.*; *Mist. Camph. ʒj. 2da q. q. hora.* He took one dose of this, and felt greatly relieved by it.

To-day he says he feels much stronger than yesterday. There are no sweats, but he does not feel cold. Skin rather hot and dry. Extremities warm. The expression of his countenance continues the same. It is very pale and thin. His whole body is very much emaciated, so that the form of the skeleton can be traced through the skin everywhere. Eyes and jaws are prominent. No dimness of sight, but all the day there has been a good deal of tinnitus aurium. His smell is unaffected, but his taste quite gone. His mouth continues very dry, and his articulation is still very unintelligible. No headache. Slight giddiness. No dreaming, wakefulness, or throbbing in the head. He slept pretty well last night. The whole body, especially the hands, seem to be affected with nervous tremors. No cough or pain in the chest whatever. Pulse 120, weaker than before. Tongue still dry and red, but no more aphthæ. Some difficulty in deglutition. Abdomen is certainly less prominent to-day, but still too full. Vocal fremitus also felt in it. Some tenderness in the left hypochondrium on deep pressure, but more in the right iliac fossa. No appetite, but a good deal of thirst. Yesterday he had rather more appetite, and was enabled to eat half a sole for his dinner. To-day he has eaten one or two cheese-cakes. They did not bring on the sensation of pain or fulness as before. Bowels not open. No pain over liver.

From this time the patient continued to become weaker and weaker. About 10 o'clock p.m. he seemed to be in excessive pain until about 2 o'clock, and groaned a good deal. He died at 3 p.m.

[To be continued.]

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 19th inst.:—Messrs. F. C. Ronalds—W. F. Dixie—S. Morris—N. H. Stevens—G. F. Lane—W. Derbyshire—S. S. Roden—A. Johnston—H. R. Stevenson—J. S. Wills.

Admitted on the 23d inst.:—Messrs. G. Salter—R. C. Perkin—J. T. Williams—G. W. Bridgeman—J. W. Keyworth—W. H. Adley—T. E. Evershed—W. S. Steele—H. J. Stormont—H. S. Gaye—R. T. Buckle—W. T. Juxton—W. Dingley.

Correspondence.

COMPARATIVE LIBERALITY OF BRITISH MEDICAL COLLEGES.

SIR,—In one of the leading articles of your journal of to-day, you remark, in speaking of the liberality and illiberality of the various British medical colleges, that “the London Colleges have taken the initiative, in liberally throwing open their examinations to the possessors of British licenses or diplomas.”

This statement however, with all due deference to you, I beg to tell you is not strictly correct, as will appear from the following:—

A short time ago, before the passing of the new charter of the Glasgow Faculty, of which I am a Licentiate, I was desirous of passing the examination of the London Royal College of Surgeons, and for this purpose wrote to Mr. Belfour, stating my wishes, and asking him whether, by presenting my Faculty License, I could be admitted for examination at the above-named College. With that polite attention which Mr. Belfour always evinces when written to, he at once replied to my question by note, informing me “that I was not entitled to offer myself as a candidate for the diploma under the circumstances mentioned,—the Faculty of Glasgow not being a College of Surgeons.” I was thus at once unexpectedly checked in my hopes of obtaining the same liberality from the London College as that which I knew they allowed to Licentiates of the Royal College of Surgeons of Edinburgh.

It is true indeed, as Mr. Belfour says, that the Glasgow Faculty is not verbally a College of Surgeons, and I know that the laws of the London College rule, that the diploma, license, or degree, presented by a surgeon already qualified, must be from one of the legally constituted Colleges of the United Kingdom, and hence I cannot complain of any fault being made in carrying out the exact wording of the law; but I can complain, and that right justly, of the spirit of illiberality and partiality shown by the College in refusing to admit for examination the Licentiate of an examining body, whose curriculum and test of knowledge is as stringent as that of any other, simply because the term Royal College does not take the place of Faculty. Still more I can accuse the College of dealing unfairly in a distinction of privilege which they make between the Licentiates and Fellows of the Glasgow Faculty itself, since they accept the certificates of Hospital Surgeons or

Lecturers, who are Members or Fellows of the Faculty, whereas their laws clearly state that no certificates will be recognised unless the surgeons or teachers be members of some legally constituted College of Surgeons in the United Kingdom. Now why, I ask, do they not follow out the strict letter of their law in this instance also, and say to all the teachers who are only Members or Fellows of the Glasgow Faculty, we cannot receive the certificates signed by you Fellows, your body not being a College of Surgeons? But this is never done, under any circumstances, and we must therefore suppose that the London College looks upon the Faculty as a College in the person of a Fellow, but as a Faculty, i. e. no College, in that of a Licentiate.

I would not have ventured so far to trespass on your valuable space, but that I was anxious to correct your notion as to the extreme liberality of one of the London Colleges in the matter of examinations.

With a feeling of pride in having the honour to belong to that body of medical men, who, though of the oldest standing, are the first to cast away ancient and ridiculous privileges, and to set the excellent example of sacrificing individual rights for the general good of the profession,

I have the honour, sir, to remain,
Your very obedient servant,
B. W. RICHARDSON,
L.F.P. & S. Glas.

Mortlake, Surrey,
July 13th, 1830.

COFFEE A REMEDY FOR HOOPING-COUGH.

DR. JULES GUYOT considers the seat of hooping-cough to be exclusively the digestive organs, particularly the stomach and pharynx; the cough and convulsive movements of the larynx being caused by pruritic irritation of the pharynx, sympathetic of the disorder of the digestive organs. The same physician has found the administration of one or more spoonfuls of infusion of coffee, according to the patient's age, after each meal, sufficient to cure the most obstinate cases. This property of coffee was discovered accidentally by Dr. Guyot while attending a very severe case of the disease.—*L'Union Médicale*.

. It may be observed that Dr. Guyot gives no facts in support of his “pruritic theory” of hooping-cough. If his views be correct, it is at least remarkable, that so closely as pathological anatomy has searched for a cause of hooping-cough, it should have overlooked what lay at the very entrance of the air-passages.

Medical Intelligence

THE GENERAL PRACTITIONERS' INCORPORATION BILL.

ON Tuesday last Mr. Wyld moved the House of Commons for leave to bring in a bill to incorporate the general practitioners of surgery, medicine, and midwifery, and said, it would not be necessary for him to detain the house more than a few moments, as he was happy to state that he had obtained the assent of the Home Secretary to the introduction of his bill. The object of his motion was to incorporate the general medical practitioners, and to give them the power to institute examinations into the qualifications of those who wished to pursue the general practice of the medical profession. He merely proposed to lay the bill upon the table, as he did not intend to take any action upon it during the present session of Parliament.

Colonel Thompson seconded the motion, which was agreed to; and leave was given to bring in the bill.

THE CHOLERA AT MALTA.

LETTERS from Malta of the 12th instant announce that the cholera was rapidly declining. Quarantine had been established at Naples of 21 days, at Leghorn 7 days, and Corfu 10 days, on all arrivals from Malta, according to the last accounts. On the 10th instant, the Governor of Malta, as President of the Council, gave the following report on the attacks and deaths from the 9th of June to the 10th of July:—Of the population, 122 attacks and 89 deaths; in the fleet, 32 attacks and 18 deaths; in the garrison, 19 attacks and 19 deaths. Total cases, 173; total deaths, 126.

PROFESSORSHIP OF SURGERY, UNIVERSITY OF GLASGOW.

WE understand that Dr. James Adair Lawrie has been appointed to the Professorship of Surgery in the University, vacant by the demise of the late lamented Dr. Burns. Dr. Lawrie has for some time occupied a similar office in the Andersonian University. The appointment is in the gift of the Crown.

EPIDEMIOLOGICAL SOCIETY.

A GENERAL meeting of this Society will be held at the Hanover Square Rooms, on Tuesday next, the 30th of July, at 8 P.M., Lord Ashley in the chair. At this meeting the following gentlemen will be nominated:—*President*, Benjamin Guy Babington, Esq. M.D. F.R.S. &c.; *Vice-Presidents*,

Addison, Thomas, Esq. M.D.; Brodie, Sir B. C. Bart. F.R.S.; Burnett, Sir William, Knt. K.C.H.; Bright, Richard, Esq. M.D.; Clarke, Sir C. M., Bart. M.D. F.R.S.; Dale, Rev. Thomas, M.A., Canon Res. of St. Paul's; Grainger, R. D. Esq. F.R.S.; Haviland, J. Esq. M.D., Reg. Prof. of Physic, Cambridge; Hastings, Sir Charles, Knt. M.D., Worcester; McGregor, Sir James, Bart. K.C.T.S.; Nussey, John, Esq. L.S.A.; Probert, John, Esq. M.R.C.S.; Roupell, G. L. Esq. M.D.; Smith, Thomas Southwood, Esq. M.D.; Sykes, Col. F.R.S.; Watson, Thomas, Esq. M.D.; Bryson, A. M.D. R.N.; Busk, G. Esq. Surgeon, Dreadnought; Bird, James, M.D.; Bell, Jacob, Esq.; Bird, Golding, M.D.; Carpenter, W. B.; Gull, W. W. M.D.; Greenhalgh, R. Esq.; Hisham, A. M.D.; Hunt, T. Esq.; Headland, E. Esq.; Jenner, W. M.D.; Latham, R. Gordon, M.D. F.R.S.; Leeson, H. B. M.D. Greenwich; M'Williams, J. O. M.D.; Marson, J. Esq. Res. Surg. Small-Pox Hospital; Parker, E. Esq., M.D.; Percival, W. Esq. M.R.C.S. Vet. Surg. 1st Life Guards; Snow, J. M.D.; Sibson, T. M.D.; Simon, J. Esq.; Sieveking, F. M.D.; Seaton, E. C. M.D.; Walsh, C. R. Esq.

OBITUARY.

ON the 16th inst., at his house at Hackney, John Mordaunt, Esq., surgeon.

Selections from Journals.

ON THE MORBID APPEARANCES IN ARSENICAL POISONING, ETC.; WITH MEDICO-LEGAL OBSERVATIONS. BY T. G. GEOGHEGAN, M.D., FELL. AND PROF. FOR. MED., ROY. COLL. OF SURG., IRELAND.

[THE following communication has recently appeared in the Dublin Medical Press, and a copy of it has been forwarded to us by the author. The paper may be regarded as a very valuable contribution to Pathology.]

The increase of the crime of poisoning of late years has become not alone a matter of serious social import, but has tended to invest toxicological inquiries with an additional interest to the physician, both in his public and curative relations. Of the various substances resorted to for criminal purposes, the arsenical compounds rank undoubtedly foremost, both as to the greater frequency of their employment, and as relates to the delicacy, variety, and gravity of the questions to which they give rise in medico-legal practice.

The great importance of the study of arse-

nical poisoning clearly appears from statistical evidence collected in England and France.

Thus of 543 cases of poisoning which formed the subjects of coroners' inquisitions in England and Wales during two years, 186 were of this nature.

Of 285 cases which occurred in France in fourteen years, 199 were arsenical.

Of 97 poisonings in Ireland which have been brought under my notice, and in which the special substance administered was determined, no less than 72 were arsenical, or three-quarters of the whole.

A case of this nature having been lately submitted to me, I propose, in the first instance, exhibiting the morbid parts to the Society,* and afterwards to offer some general observations on the appearances which have presented themselves in other instances which I have investigated, together with some additional remarks on certain other points in the history of arsenical poisoning. The specimen laid upon the table is the stomach of a female past the middle age, who died from the effects of arsenic under the usual symptoms of gastro-intestinal irritation, after an illness of sixteen hours. The organ having been transmitted to me with a view to the detection of the poison, I observed the following appearances a week after death, at which period the body was exhumed, and found free from any trace of putrefaction.

The peritoneal coat presented a diffused, red, and towards the splenic end a brownish tint. There was a marked contraction of the muscular coat about three inches from the pylorus. An uniform reddish fluid (twelve fluid ounces), of the consistence of thin gruel, and depositing brown flocculi, formed the contents, which were of an acid reaction, indicated freely the presence of arsenious acid in solution, and included a considerable quantity of insoluble hæmatosine. The mucous membrane was found at the splenic end of a mottled reddish brown colour, covering a stratum of coarse ramiform vascularity (in the submucous tissue), soft, and presenting a few petechial ecchymoses, and one or two erosions (of the area of a fourpence), with an undefined border, which exposed the unaltered submucous coat. The body of the organ (as far as the contraction) exhibited a remarkable arrangement of dark blackish purple streaks of extravasated blood, deposited in the substance of a softened mucous membrane, and capable of ready removal by the nail, which laid bare the sound submucous texture. These streaks (which affected for the most part

the direction of the long axis) were of trivial thickness, scarcely elevated, flattened on the surface, and made up of a close aggregation of irregular blotches. Amongst these lines there were interspersed a few of the lighter-coloured *petechial* (fluid) ecchymoses, observed at the splenic end. The remainder of the mucous membrane was of a brown red, which abruptly ceased at the contraction, between which, and the pylorus, the membrane where untinged by bile was grey, and coated with viscid opaque mucus of the same colour. The mucous membrane generally was softened, not capable of being peeled off at the splenic end, but yielding on traction in the body and towards the pylorus, flaps of one quarter and half an inch respectively. The submucous coat, except at the great tuberosity, seemed free from injection. There was no trace of true ulceration in any part of the organ. The mucous membrane of the *duodenum* was reddish, and apparently a little thickened, and presented an oval ulcer of the size of sixpence, with a thick elevated edge, its surface exposing the submucous, and in the centre the muscular coat. As the patient had previously complained of pain in the region of the stomach, it is probable from this (and other considerations) that the above ulcer was the result of antecedent disease.* The softening of the mucous membrane in the present case seems referable to the prolonged action of the contents during a week's inhumation, and not to the influence of the poison, which, in my experience, has not been observed to produce that effect. The heart and lungs were reported in the present case to have been natural. The stomach at the end of four weeks was scarcely altered, as I shall further explain when alluding to the antiseptic influence of arsenic. I shall now proceed to the general consideration of the morbid conditions which obtain in arsenical poisoning, confining myself on the present occasion to the stomach, both as being the organ which presents the most striking and varied appearances, and being also that which I have enjoyed the most extended opportunities of examining.†

* I examined not long since the duodenum of a gentleman between twenty and thirty years of age, who died of perforating ulcer of that part under circumstances incompatible with the supposition of poisoning.

† It is much to be regretted that the post-mortem inspection in cases of poisoning is too generally confined by practitioners to the abdominal cavity, and in some cases to the stomach alone, and thus that much matter of great interest and importance in medico-legal history is lost. The appearances which I have had occasion to observe in the heart, lungs, and blood, have been in some cases remarkable. In the first, endocardial (petechial) ecchymoses in both ventricles; in the lungs, intense congestion, approaching in appearance to pulmonary apoplexy

* Read before the Surgical Society of Ireland, Jan. 26, 1850.

The morbid alterations produced in the stomach by the action of arsenious acid, arising as they do either from its local influence as an irritant, or indirectly from its absorption, and being independent of any corrosive agency,* cannot of course be considered distinctive. From this circumstance, however, they are well fitted to convey to the inexperienced examiner a correct idea of the appearances to be expected in irritant poisoning at large. To these common signs there are occasionally superadded some of a peculiar nature, arising out of the physical properties of arsenic, to be afterwards described. The following results have been arrived at from the examination of sixteen fatal cases:—

1st. All (with one exception, in which maceration had altered the parts,) exhibited signs of irritation in the form either of—*a*, vascular injection, *b*, ecchymoses, or *c*, colouration. The mucous membrane was engaged in fifteen; the submucous coats also, in five; the peritoneal in two; and the venous arrangement of the great extremity in one case.

The ramiform vascularity I have only found in the submucous coat, which seems also not subject to any of the other varieties of injection. The punctiform, or closely stellate, is by far the most common variety, occupying extensive tracts of the mucous surface, and either uniformly distributed, or disposed in sinuous lines or scattered patches. The striated vascularity I have met with but in one instance.

2nd. Diffuse redness, although more frequently present, according to my experience, than any other deviation from the natural state, I have not enumerated under the head of vascular injection, since, without denying its occasional morbid character, I feel disposed to view it as a pseudo-morbid change resulting from the influence of transudation and imbibition on the punctuated vascularity. Accordingly, I have

and general bronchitis, which latter I have more than once found indicated by physical signs during life. The condition of the blood I have found variable, sometimes coagulated in the heart, and fluid in the great veins (as happens in various other forms of death), and occasionally viscid in the pulmonary vessels. In one instance, examined ten hours after death, the fluid blood removed from the venous system coagulated in the receiving vessel, affording a milky serum.

* In the common acceptance of the term "corrosion," which is understood to imply such chemical action as issues in alteration of the colour or consistence of the part: it is not, however, to be inferred from the absence of the latter results, that no chemical influences are mutually exercised by the poison and the mucous membrane: such, in the case of arsenious acid, are most probably in operation, and for aught that can be affirmed to the contrary, may be the cause of its irritant action on mucous, and its sphaculating effect on ulcerated surfaces.

observed the latter to degenerate into diffuse redness by the influence of time and exposure to the action of the stomachic contents. The diffuse redness may exist alone or in combination with other results of irritation.

3rd. Ecchymosis as a consequence of arsenical poisoning has presented itself to my observation under the form of—*a*, well-defined blotches, oval, angular, or circular, and generally small; or *b*, of lengthy streaks, parallel or areolated. Both are formed of a thin stratum of altered, nearly black, and apparently coagulated blood, deposited in the tissue of the mucous membrane. They are scarcely elevated, and (the mucous membrane at the point occupied being much softened) are readily removed by gentle scraping, leaving behind an *erosion* of corresponding figure. A variety of ecchymosis which I venture to designate the *petechial* (seen in five cases) is essentially different from the foregoing. It consists of invariably small and rather florid blotches of fluid blood, thinly scattered for the most part on the summits of the rugae, and unaccompanied by softening of the membrane. This condition might be confounded by the inexperienced observer with the punctuated injection, from which, however, it is readily distinguished by the lens, which reveals the vessels of the latter.

The ecchymoses just described do not appear to me to result, as might be supposed, from the lodgment of small masses or particles of the poison on the mucous surface, which I have not observed in any instance. On the contrary, I have seen them produced by fluid poisons, as ardent spirits, &c., which can only act by creating a violent determination of blood to the entire surface, and consequent rupture of the weaker vessels. One at least of these conditions may moreover exist under circumstances in which the poison could have only reached the affected part by absorption; as in the external application of arsenic, or where the spots involve the endocardial membrane. The only effect which I have observed as strictly traceable to the *local* action of arsenic on the mucous coat, is a fungous thickening (forming an elevated ridge or circular raised patch), with or without the effusion of lymph, and surmounted by adherent arsenic.*

It is possible that the non-occurrence of sloughing of the mucous membrane, from

* In one case (fatal in twelve hours) numerous patches of tough, coriaceous fibrine, some of them of large size, were discovered strongly adherent to the mucous surface, which, to a corresponding extent, was intensely vascular and greatly thickened. In another there were two ridges much elevated (formed solely by the lining membrane), and crested with a mixed coating of arsenious acid and mucus.

the local contact of arsenic, is due either to its high vitality, or to a partial protection of its surface by these mucous or fibrinous effusions.

4th. Erosion of the lining membrane I have met with in one-fourth of the cases examined, and under two forms. 1. The circular. 2. Long narrow sinuous streaks. Both expose the submucous coat. The former, which generally occupies the splenic end, presents a soft undefined nonelevated margin free from red colouration. The margins of the eroded streaks, on the contrary, are sharp. A careful examination of these erosions has impressed me with the belief that they are produced by the removal of the mucous membrane where occupied by the black extravasation. Accordingly, they can be produced by gently scraping the latter; and in one instance (fatal in thirty-six hours) in which I found extensive linear erosion, a portion of the eroded surface was found still coated with the black matter.

I have never encountered true ulceration of the stomach in arsenical poisoning, although I have seen it extremely well defined on the posterior part of the buccal mucous membrane (in a case fatal in four days and a half.)

I have not been able to trace *softening* of the mucous tunic to the action of arsenic, not having seen it in cases examined sufficiently early to preclude the possibility of its pseudo-morbid origin. From the great tenuity of the membrane at the splenic end, a very short contact with the contents will suffice to produce considerable softening, particularly when the latter (as often occurs) have a decidedly acid reaction. In such I have witnessed from the latter cause, in arsenical poisoning, another pseudo-morbid change; namely, extensive brownish black staining of the mucous surface of the splenic end, similar to what is occasionally seen from the action of oxalic acid. This arises from the influence of gastric acid (lactic?) on the blood contained in the highly inflamed mucous surface; and a like colour is imparted to the contents when bloody. Although softening of the mucous membrane appears not an unequivocal result of the influence of arsenic, to the latter it may be referred.

4th. *Diminished adhesion* of the mucous to the submucous coat. This is best observed at the pyloric third, where traction will often furnish a flake of an inch and a half to two inches in length, being probably three or four times the natural amount.

Having spoken of the mucous and submucous membranes, I have only to state, that in two instances I have observed diffuse red colouration, and in two, capillary injection of the peritoneal coat, without effusion of fibrine or serum.

The examination of the physical characters of the stomachic contents is a matter of much importance in medico-legal inquiries, and will be often found to elucidate, in a most unexpected manner, questions which may involve the life of an accused party. Thus, in one instance which fell under my notice, the determination of the nature of a solitary seed found on the mucous surface became of serious moment. In another, the discovery of grains of shot in the colon, furnished me the means of affording sufficient legal evidence for the identification of a body buried several weeks, in which there had been no label affixed to the coffin, and where the countenance was too much altered to be recognized. Except where the contents deposit grains of arsenic (which I have met in two cases), they do not for the most part present anything to distinguish them from those observed in other forms of non-corrosive irritant poisoning. For the more accurate information, however, of the inexperienced inquirer, I subjoin* the numerical results of the conditions observed, premising that the most usual combinations of them are, probably—1. The thick, and turbid, and bloody (insoluble hæmatisine); and 2. The copious, viscid, and bilious (brown or green). In alluding to the pseudo-morbid changes produced in the stomach at ulterior periods, the modifying influence of putrefactive gases on deposited arsenic, and the consequent formation of sulphuret of arsenic, need scarcely be alluded to, being now well known to medical jurists. A condition, however, of the mucous membrane has presented itself to my notice, which is capable of leading to mistake—namely, a copious deposit of adherent yellowish white crystals of *phosphate of magnesia and ammonia* on its surface. This occurred in a case of arsenical poisoning exhumed after forty-seven days, and was evidently a post-mortem change, as it was present also in the lining membrane of the heart.†

The peritoneal surface also of the liver, in contact with the stomach, in some instances, presents a deposit of a white granular matter (which, in a case of arsenical poisoning, I have known mistaken for arsenic supposed to have transuded). This I have found to consist of *sulphate of lime*. Its mode of production is not very apparent.

Although it is no part of my present

* In sixteen cases the contents were—in 11, bloody; 9, turbid; 6, viscid; 6, thick; 5, bilious; 4, flocculent; 3, acid; 2, rancid; 2, foetid; 1, intensely so, without putrefaction, and apparently from stercoraceous regurgitation; 1, coffee-coloured.

† Professor Apjohn has described a similar condition of the peritoneum.

purpose to enter into the subject of the detection of the poison, I shall conclude the notice of the stomachic contents by observing generally, that the mode of combination of the poison (when discovered) is also liable to alteration through the influence of circumstances which have come into operation antecedent to death. Thus I have seen one instance, in which arsenious acid, taken by a suicide, became converted into arsenite of copper by the antidotal employment of sulphate of copper followed by albumen. Arsenious acid is, however, exempt from those alterations resulting from the action of animal fluids and tissues, which sometimes create difficulty in the case of other mineral poisons.

(To be continued.)

ABSTRACT OF THE FIFTH SERIES OF PROFESSOR MATTEUCCI'S ELECTRO-PHYSIOLOGICAL RESEARCHES.

PART I.—Upon Induced Contractions.

THE experiments detailed in Signor Matteucci's former researches, proved that no signs of an electric current are manifested during the contraction of the muscles, and therefore that induced contraction cannot be referred to that agency. The following new researches were instituted with a view to the discovery of the nature of the phenomenon of induced contractions, which is so obscure and at the same time so important.

Observing that the slightest discharges from a jar, inappreciable by the most delicate of our electroscopes, are invariably sufficient to excite violent contractions in a frog, it appeared agreeable to analogy to suppose that the cause of induced contractions might reside in a discharge similar to that of the jar, taking place in the muscle in the act of contracting. If that had been the case, it would no longer have been a matter of surprise that the galvanometer should give no indication during muscular contraction.

Very slight discharges, such as are elicited after a very small jar has been discharged two or three times with a metallic arc, were passed through an insulated galvanoscopic frog, the nerve of which touched the muscle traversed by the discharge.

Thus it is shown, that in spite of the good conductivity of muscle, a part of the discharge escapes to the surface and traverses the nerve of the galvanoscopic frog.

This phenomenon is still more remarkable when the nerve of the galvanoscopic frog is laid out on a metallic surface, through which the shock is passed. The same phenomenon was manifested when a non-conducting medium, as a layer of turpentine of such depth that a current from a pile of fifteen couples of plates could not penetrate

it, was interposed between the muscular mass and the nerve of the galvanoscopic frog.

The interposition of very fine plates of mica did not prevent, though they diminished, the frequency of the contractions.

By exposing the nervous centres of animals, and placing these in contact with the nerve of the galvanoscopic frog, and exciting muscular contractions and other manifestation of the nervous force, no contractions were excited in the galvanoscopic frog: while on the other hand, contact of the galvanoscopic frogs with the muscles of the same animal when in a state of contraction, induced contraction through their nerves.

Hence it is inferred, that the phenomena of induced contraction belong exclusively to the muscle in the state of contraction. But it is impossible to determine by direct experiment whether induced contractions be due to electric discharges produced during the contraction of the muscle.

PART II.—Upon the phenomena elicited by the passage of the current through the Nerves of a living Animal, or an Animal recently killed, according to the direction of the current.

The direct electric current transmitted along the course of a nerve exhausts its excitability; the inverse current increases it.

The following experiment illustrates this part of the subject, which has been studied in all its bearings by Signor Matteucci. The frog prepared in the usual way is placed astride between two little glasses in which the rephores of a Faraday's pile of fifteen or twenty elements were immersed. It is evident that one of the limbs is traversed by a direct current, and the other by an inverse current.

In the first place, the two limbs contract both on closing and on opening the circuit, after which there is contraction of the limb traversed by the direct current on closing the circuit; and the other limb contracts on breaking the circuit; finally, only one limb contracts, viz. that of the inverse limb on the cessation of the passage of the current. On keeping the current closed for some minutes, we invariably remark that the inverse limb, which contracts on breaking the circle, is seized with a permanent contraction of a decidedly tonic character. This phenomenon is of importance, as it indicates an intimate connection between nervous influence and the action of the electric current, according to the direction of the latter.

The phenomenon manifests itself after the current has been passed for twenty-five or thirty minutes. It occurs equally on passing the current through the nerves

without its traversing the muscles; but never when it passes through muscle alone. If while the circle remains closed, and it has been previously ascertained that the tetanic contraction will follow the opening of the circuit, the nerve be divided rapidly at the precise point where it enters the muscle, the limb is thrown into contraction without its remaining in a state of tetanus. If, instead of this, the nerve be divided higher up near to its issue from the spinal marrow, then the tetanic contraction takes place as usual.

The previous exhibition of narcotics to the extent of narcotism, prevents the tetanic contractions. The passage of the inverse current, the same by which the phenomenon is produced, puts a stop to the tetanic contractions in two or three seconds. If the direct current be passed, it ceases in two or three minutes. The same phenomena occur in warm-blooded animals, only of shorter duration. No electric current is in circulation in the nerves, neither is any electricity rendered latent by the passage of the inverse current. The phenomenon in question belongs to the yet undetermined relation which exists between nervous influence, and the action of the electric current according to the direction of the latter.—*From the Philosophical Transactions.* x

CAUSES OF DEATH.

ALL CAUSES	863
SPECIFIED CAUSES	858
1. Zymotic (or Epidemic, Endemic, Contagious) Diseases....	198
Sporadic Diseases, viz.—	
1. Dropsy, Cancer, &c.	52
2. Brain, Spinal Marrow, Nerves, and Senses	117
4. Heart and Bloodvessels.....	31
5. Lungs and organs of Respiration	89
6. Stomach, Liver, &c.	72
7. Diseases of the Kidneys, &c.	10
8. Childbirth, Diseases of Uterus, &c.	3
9. Rheumatism, Diseases of Bones, Joints, &c.	10
10. Skin.....	3
11. Old Age	37
12. Sudden Deaths.....	6
13. Violence, Privation, Cold, &c....	24

The following is a selection of the numbers of Deaths from the most important special causes:

Small-pox.....	3	Convulsions.....	34
Measles.....	16	Bronchitis.....	1
Scarlatina.....	13	Pneumonia.....	45
Whooping-cough.....	23	Phthisis.....	107
Diarrhoea.....	51	Lungs.....	4
Cholera.....	5	Teething.....	15
Typhus.....	31	Stomach.....	5
Dropsy.....	20	Liver.....	8
Hydrocephalus.....	36	Childbirth.....	3
Apoplexy.....	11	Uterus.....	4
Paralysis.....	27		

REMARKS.—The total number of deaths was 110 below the average mortality of the 29th week of ten previous years. The mortality of London exhibits a slight increase this week; this is found to have obtained in the zymotic or epidemic classes of disease, and more particularly in diarrhoea, among infants: thus, in 53 cases of this disease, 35 occurred in infants, and 8 under 10 years of age. Of five cases of cholera reported, four also occurred in infants. One case only is denominated "malignant," the other cases being English cholera. Other epidemic diseases have perceptibly declined.

NOTICES TO CORRESPONDENTS.

The First Report of the Metropolitan Sanitary Association has come safely to hand, and shall receive our early attention.

Dr. G. Merryweather.—We will find room in our next number for an extract from the paper forwarded to us. Our space will not allow us to do more than this.

We shall commence the publication of Dr. Jamieson's Lectures on the Medical Jurisprudence of Insanity next week.

Mr. Galtrey's third communication has been received. We cannot yet fix the time for commencing the series of papers; but due notice shall be given to our correspondent, and a proof sent to him a week before publication.

The papers of Mr. Balman, Mr. W. Addison, and Mr. Grantham, will appear in the following number. Proofs will be sent.

RECEIVED.—Dr. James Esdaile (Calcutta).

Lectures.

LECTURES

ON THE

MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.

Lecturer on Medical Jurisprudence in the
University.

LECTURE I.

*On the relation of insanity to certain allied
conditions—Resemblance of insanity to
dreaming, febrile delirium, and delirium
tremens—these occasional causes of the
disease—Excited passion and insanity—
Psychological character of insanity—
Insanity contrasted with illusion, hallu-
cination, delusion, disease with mental
symptoms, intellectual dulness, eccen-
tricity, abused fancy, and moral de-
pravity—Pathology of insanity.*

MEDICAL and legal doctrines on the sub-
ject of diseased mind are even in this pre-
sent day far from harmonious, and there-
fore in teaching you what is termed the
medical jurisprudence of insanity, I shall
consider it right to occupy not a little of
the time with a detail of the features of
mental derangement, so as to afford you a
just notion of what the lunatic condition
actually is, and put you in a position to
form independent judgments on the points
which are referred to medical opinion. In
so doing, while I shall seek to avoid all
pathological and therapeutic matters as
unsuited to the objects of such a course, it
may happen, in regard to most of you, that
I shall be effecting something in the way of
filling up what is ordinarily an unfortunate
hiatus in the education of the profession.

Insanity is one of several states of im-
perfect action to which the organism of the
human brain is liable. Among these I may
enumerate, for example, the conditions of
dreaming, and the several varieties of
delirium, all of which are forms of mental
unsoundness, having certain common re-
semblances, and bearing undeniable rela-
tions to the state of mind which exists in
the insane. They are all conditions in
which certain faculties of the mind are in
abeyance, and in which, as a necessary
consequence, psychical manifestations are
perverted or imperfect.

Dr. Holland is of opinion that more

cases of insanity bear a similarity to the
mental phasis which constitutes dreaming,
than to any other cerebral condition what-
ever; and certainly there are no observa-
tions in our power to make, that seem to
convey so distinct an impression of the
sensorial state of the insane, as those which
an individual may attempt, by turning his
attention upon what takes place in his own
mind when merging into the sleeping or
the waking state. In the transition be-
tween these two conditions the mental op-
erations have many features in common with
delirium and intellectual derangement. As
the senses are gradually released from sleep
or overcome by it, the succession of thoughts
is slowly emancipated from control; the
ideas are combined in a manner which is
altogether involuntary and dissimilar to the
ordinary workings of the imagination. Con-
ceptions take the place of sensations, as
in the insane, and sensations become misin-
terpreted, as happens in cases in which the
judgment is diseased. If the train of
thought were expressed, it would be in
speech as rambling and incoherent as the
raving of the demented. The cerebral
condition in dreaming is so far allied to
that of insanity, that occasionally a state
of painful dreaming gives the first warning
of approaching mental disease, and the pa-
tient seems to suffer from the disorder in
"the howling wilderness of sleep," for some
time before it has gained sufficient energy
to influence the powers of volition and
judgment when he is awake. I have occa-
sionally heard an attack of insanity attrib-
uted to a frightful dream, the delusion
that afterwards haunted the mind traced
to an impression produced in this way, and
in some cases have known the state of in-
sane to spring apparently directly from
that of sleep.

The following seems an example of a
cerebral condition induced by sleep merg-
ing into that of insanity, the patient going
to bed sane, and awaking lunatic:—A
female servant in the country, a robust
young woman, about twenty-seven years of
age, in whom no mental peculiarities had
ever been observed, came down stairs from
her sleeping apartment one morning com-
plaining of headache, and inability to go
about her ordinary occupation. She exhib-
ited much excitement of manner, and
confusion in her talk, and repeatedly called
out for her master's son, who she insisted
had been with her during the night, and
had promised her marriage, or, as she
phrased it, had married her before God.
Circumstances were every way at variance
with the possibility of her story, and her
whole appearance and conversation were
manifestly those of a person labouring
under an insane delusion. Attempts were

made to reason her out of the notion, but in vain. Continuing to become worse, she was sent home to her friends, and put under medical treatment, with so much advantage, that in a few weeks she was allowed to return to service. Her old place, however, very speedily caused the delusion to be renewed in all its force, and she was again returned to her friends, with whom she continued for some months, constantly manifesting the same monomania. She then came under my charge; but it was some months before she recovered, and became aware of the extent to which she had been deceived by her own imagination. A year or two afterwards, when she was in a different part of the country, I am given to understand that the same fancy returned very suddenly when she was in a stooping position cleaning a grate.

The state of dreaming resembles that of delirium or insanity, in a similar disturbance of the laws by which ideas succeed each other in the mind, and a corresponding loss of voluntary control over the trains of thought. Hence the intellectual manifestations of memory and comparison are impaired in both states: conceptions become sensations, constituting dreams to the sleeper, and delusions to the lunatic. If the dreamer added the fancies of his sleep to his waking experience and belief, as an insane person not unfrequently does, and as appears to have happened in the case just narrated, he would in no way differ from the latter.

Between febrile and maniacal *delirium* the distinction seems to be entirely pathological: psychologically they are the same. In the former, the vital functions of the great nervous centre are more deeply implicated, and it is from this character that a diagnosis is best deduced. Either state may pass into the other, the delirium of fever becoming mania, and the delirium of mania assuming an appearance which corresponds to the nervous symptoms in the worst description of typhus. Such changes are effected not by any alteration of the mental, but of the physical symptoms of the disorder. If a fever patient continues to labour under delirium after all other febrile symptoms have abated, he becomes a lunatic patient, and will have to pass from the fever hospital to the asylum. This forms the occasional history of a case of insanity, and most commonly in young persons. The variety of insanity assumed is generally that of dementia, and the recovery, though tedious, is not improbable.

A carpenter's apprentice, aged seventeen, was attacked with the usual indications of fever of a low type. The case throughout was marked by the predominance of symp-

toms referrible to the nervous system; the skin was very hot; the pulse feeble and quick; the tongue dry and brown; there was much subsultus, and delirium was very persistent. In the course of three weeks all the febrile symptoms had abated; the skin was cool; the pulse at a natural standard, and the appetite restored; but the eyes had a very wild expression; he could not be prevailed upon to answer questions; he was violent and unmanageable, without indicating any reason, or making any complaint. Though his strength was daily improving, and his bodily health apparently restored, the mental symptoms became more and more urgent; and he was considered to be insane, and put under superintendence accordingly. The exact state of his mind could not be ascertained, for he scarcely spoke for several months, but his actions were very extraordinary, and apparently influenced by spectral objects and aural impressions. His recovery occupied a period of fourteen months.

You will find several interesting examples of delusion and mental disease combined with, or resulting from, fever, in Roupell's *Treatise on Typhus*.

The change from a state of maniacal excitement to one resembling the delirium of typhus, is familiar enough to the superintendents of lunatic hospitals, as of occasional occurrence towards the fatal close of cases of violent and acute mania. In such instances the patient seems to die entirely of the vital exhaustion which is produced by extreme excitement of the nervous system, and an individual, seeing the case for the first time at this stage, might from the symptoms suppose it to be one of malignant fever.

Between the mental condition of *delirium tremens* and insanity, there seems to be no other difference than what is made by duration. If the patient, labouring under symptoms of a certain sort, die or recover within a reasonable time, say two or three weeks, he is said to have had delirium tremens, but if the delirium persist beyond some such period, the case becomes one of mental alienation, and is dealt with accordingly. Such is the history of very many cases of insanity which have had their origin in intemperance.

Besides the above conditions, there are several other states and moods of the mind to which insanity has kindred features; in which there is in degree a similar loss of power over the thoughts, with inefficiency of judgment, and even illusions of sense. Anger, fear, grief, enthusiasm, and excitement of the imagination, may put a fool's cap for a time on the wisest head, producing states that differ from unsoundness only in the shortness of their duration, and

the possibility of their being rectified by voluntary effort.

Insanity bears resemblances to various conditions, and presents itself in a variety of forms. Sometimes it is congenital, and consists of undeveloped faculties; the powers of the mind have never been completed, or they have never acquired the energy necessary to manifest themselves in natural activity. Sometimes it mainly assumes the form of ungoverned passion and loss of moral control. Another time it resembles delirium, and consists in intellectual disorder and confusion; and lastly, it may arise from destruction or obliteration of one or more of the faculties of the intellect. In all instances the characteristic is defect of mental power, either congenital or the consequence of debilitating causes. The power which is deficient is the controlling power of the will, as exercised over the current of thought, the relation through which every mental operation is produced. All imperfect mental actions result from this cause, but none of these are denominated insanity unless that imperfect action which has either congenital defect or disease as its cause, and for its sign a relative or an universal incapacity of judging. Observe, I do not say an incapacity of judging correctly, but an incapacity of judging at all: the former would merely indicate imperfect thinking or error, but the latter indicates disease. The loss of the power of judging is exhibited in matters of sense, in matters of conduct, or, it may be, in every matter with which judgment should be concerned. Suppose it to be a diseased perception that cannot be canvassed by the judgment, then the phasis of the insanity is intellectual, and its leading symptom delusion; but should it be an emotion that is diseased, then the moral aspect of the individual is unsound, and the prominent feature a loss of control over actions; and instead of a calm judgment guiding the conduct, you may have an impulse as resistless as a necessity, unassailable by reasoning, and removable only indirectly by treatment.

To constitute insanity, then, it is necessary that a diseased condition of the mind interfere with the production of that result of the comparison of one thought with another which we term judgment. We cannot, in the estimation of Dr. Connolly, approach any nearer to a definition of the state, than by saying, that it is an impairment of one or more of the faculties of the mind, including or inducing a defect in the comparing faculty. Until the morbid action is thus powerful, or thus much extended, it is not insanity. Diseased perception may produce illusion or hallucination, but so long as the power of com-

paring it with other perceptions is intact, and entire, the false impression is corrected, and has no influence, but a voluntary one, upon the conduct. Even should the illusion continue, its inconsistency is more apparent to the judgment, than its existence is clear to the sense. In such a condition an individual possesses a phantasma, but is not possessed by it; it is under the control of his higher faculties: he can compass it about, and deal with it as he pleases. An insane person finds no curative incompatibility with other perceptions in his delusion, because he has no power of instituting the comparison. It controls his will, but his will has no reaction upon it; and he remains possessed by it, and insane, until such time as his volition is enabled so to handle his morbid idea, as to make it subservient to comparison and judgment.

Illusion, hallucination, and delusion, though usual phenomena in insanity, are not sufficient to constitute the disease. These terms are of common occurrence in medical writings on the subject, and are not always used very categorically. An *illusion* is a mistake of the senses, a false perception; a *hallucination* is a baseless creation of the fancy; a *delusion* is an illusion or hallucination misleading the judgment, and governing the conduct. Thus, if a person returning home at night mistook the trunk of a tree for an apparition, that would be an illusion; if he saw a ghost where there was neither tree nor anything else, that would be a hallucination; if he believed in the reality of this conception, he would be under a delusion; and if he continued to act in accordance with such a belief, he would be as one insane, yet not truly mad so long as his obedience to it remained a matter of his own free will.

A careful distinction must be made betwixt diseases having mental symptoms, and diseases of the mind; betwixt madness, and such affections as hypochondriasis and hysteria. Hypochondriasis consists of illusions and hallucinations regarding one's bodily sensations, and is therefore not insanity, until these become deep-seated and permanent delusions, compelling to irrational conduct. Hysteria, hypochondriasis, and various other affections, which often precede, cause, and accompany insanity, are not diseases of the mind, but more strictly speaking diseases having mental symptoms, until by generating delusions they pass into insanity, and afterwards continue as complications of the disorder which they have created. Thus we have hysterical mania, which is not hysteria merely, but hysteria and mania combined; so also there is hypochondriacal monomania, which is not hypochondriasis alone,

but hypochondriasis and insanity together.

Simple defect of intellectual power, *intellectual dulness*, must not be confounded with the imbecility which constitutes a variety of insanity, which is not merely a feeble intensity of mind, but a positive deficiency of faculties. Wherever there is a feeble exercise of attention, or defective memory, there will be imperfect comparison, and resulting inaccuracy of judgment; but not from these, or similar causes, any necessary tendency to be governed by delusions. In all cases of imbecility included in the term unsoundness of mind, there are both emotional and intellectual deficiency, a loss of control over conduct, and from the antecedence of judgment being in some part defective or diseased, a liability to confound the actual with the unreal. Delusion is not a prominent characteristic, however, for in such cases feebleness is the type of all the mental manifestations, whether healthy or disordered.

Eccentricity has also to be distinguished from insanity. All the insane are eccentric in their ideas, their language, or their conduct, but the merely eccentric have but a voluntary resemblance to the insane. Eccentricities differ from lunacies in not arising from a loss, but from an undue exercise, of the faculty of judgment; very often from a vanity or self-respect in the individual, that leads him to prefer his own judgment to all other judgment, experience, and authority. They offend against custom and experience more than against reason. The eccentric, if he cannot give a satisfactory reason for his *outré* conduct, can at least assign an intelligible motive: the lunatic has no explanation to afford that does not involve an absurdity. A certain individual behaves in all respects like other men, unless that he constantly walks about without a hat, or any other artificial covering for his head. When questioned upon this point of disagreement with the custom of his neighbours, he says, that nature did not intend the head to have any other protection than what she herself had afforded, that a bare head is more becoming, that he feels himself in every way more comfortable as he is, and that he is certain that he will live longer in consequence of acting in this rational way. In two instances in which lunatics adopted the same habit, the causes assigned by them were of a very different description. One did not have his head covered, because it had grown so large that he could not get a cap to fit it; and the other was so annoyed by certain mischievous tormentors of an invisible kind drumming upon the crown of his hat, that in general he preferred to carry it in his hand. The eccentric man had a rule of

conduct, the result of his own narrow judgment; the two lunatics were impelled by fancies upon which their judgment was entirely inoperative. Lord Monboddo, insisting that the human family were originally adorned with tails, showed himself an eccentric theorist: had he asserted that they actually retained them, he would have had an insane delusion, instead of a philosophic crotchet. He would have had a false perception on which his judgment was inoperative, whereas, he was guided by his judgment to a strange conclusion.

Eccentricities no more constitute insanity, than idiosyncrasies constitute disease; and as these are competent with a sound state of the body, so are those with even a vigorous judgment. For example: there was an old man well known in London in the last century, who was of an ungainly appearance, and subject to occasional attacks of a hereditary melancholy. So inconsistent was he in his habits, that sometimes he practised great abstemiousness, and at other times devoured huge meals, with brutish slovenliness and voracity; sometimes he would persist in drinking nothing stronger than water, but occasionally he drank wine by tumblerfuls. His income was far from large, and not of a certain amount, yet he kept a set of old men and women about his house, whose bickerings and disagreements now and then drove him out of doors. He was in general very loquacious, but had been known to sit in company and drink a dozen cups of tea, without speaking a syllable. When not engaged discoursing, it was his custom to keep muttering to himself. In walking, he performed strange gesticulations with his limbs, and would not go in at a door, unless he could effect his entry in a certain preconceived number of steps, and so as to introduce himself on a particular foot, turning back, and recommencing, until he succeeded as he desired. There was a row of posts near his house which he would not pass without touching singly, and if he found that he had omitted one in the series, he retraced his steps to remedy the neglect. He hoarded up orange-skins for some mysterious purpose which he would never divulge. He suffered remorse of conscience for once having taken milk with his coffee on Good Friday. He believed in ghosts, and went ghost-hunting in Cock-lane; and he maintained that he had heard his mother calling upon him by name from the other world. Yet Dr. Johnson was so far from insane, that his judgment commanded respect and admiration everywhere, and by the common consent of eminent contemporaries he was the most vigorous thinker and the greatest sage of his time.

There are, however, instances of eccen-

trick conduct resulting from *abuse of the imagination*, which verge closely upon madness, and occasionally pass into it. The distinction is, that the individual's voluntary power over his thoughts is capable of bringing the comparing faculty into efficient operation, when he chooses duly to exert his will. Thomas Hood speaks of one who, in consequence of exciting his fancy by German tales of diablerie, used to fly up stairs at his utmost speed from the street-door to the attics, because a sort of wager with the devil came into his head, that he would gain the top before counting a certain number, or forfeit eternal happiness. Every one possibly experiences moods which differ in no respect from insanity, than that they are neither permanent nor independent of the will. These may be common in imaginative minds, but instead of being indulged, they should be guarded against and restrained, for, though they exist at first by sufferance of the will, they sometimes gain a strength that defies control, and triumphs over the reason. Hoffmann, a master in fantastic fiction, suffered so much from intemperate abuse of the imaginative faculty, that solitude became terrible to him. He was never quit of a mysterious sense of danger; things the most cheerful became incongruously associated with thoughts the most dreadful, while monsters and spectres, which he himself had created, tyrannized over his reason. To appease his terrors, he had frequently to summon his wife from bed, to sit by him as he studied at night. He was constantly on the verge of insanity, and died of spinal disease, his mind being tortured by his fancy to the last hour of his existence.

Often it is not an easy matter to draw a distinction betwixt insanity and *moral depravity*. In every case of mental alienation there is disorder of moral as well as of intellectual manifestations. The moral disturbance is usually the earliest developed feature of the malady, frequently it is the most prominent, and occasionally no other is distinguished; so that the bad have been liable to pass as mad, and the mad for bad, according to the philosophy and fashion of the time. There is no problem in law, medicine, and ethics, of greater social importance, or of more difficult solution, than the discrimination of insanity and vice. A wicked deed may be the result of an undeveloped moral sense, as for example in a child or an idiot; it may be the consequence of such extremity of passion as impels to instinctive, instead of deliberative action; and it may be the indication of a conscience enfeebled by voluntary neglect, and the habitual gratification of evil desires. Any of these states may be simulated by disease; but it is with the two

last only that the jurist will have difficulty; for, in all cases of insanity in which the moral sense is non-existent, the powers of the understanding also are either undeveloped or destroyed. No hideousness of depravity can amount to proof of insanity, unsupported by evidence of a judgment incapacitated or a will fettered by disease. In those cases of mental disorder in which the emotions are perverted, and where there is no clear proof of deranged intellect, cases which do from time to time occur, the presumption of insanity, in regard to a criminal action, has to be upheld by evidence of suspension of the will. The actions of an individual in such a state ought to be impulsive, involuntary, and irreconcilable with the idea of a healthy state of the emotional faculties.

I have endeavoured to draw as plainly as possible certain distinctions betwixt insanity and some conditions which, as they are allied to it, are sometimes confounded in it. Let me now request your attention, in conclusion, to a few remarks on its essential nature as a disease. I have already spoken of its psychological character. As a pathological state it is easier to tell what it is not, than what it is. Some will have it to be a disease of the body, in which metaphysics are useless; others, a disease of the mind, to which physic is as inappropriate. Still we find it curable sometimes by moral treatment, sometimes by medical; but far more usually by a judicious combination of the two, and almost never remedied by unassisted nature: a truly impresible condition, and far from an opprobrium medicorum. It is not a purely corporeal disease, like one of the neuroses; it is not a nervous affection merely, but a neurosis and something more; neither is it a purely mental affection, like error or vice. Both mind and body are at fault. According to the views of Feuchtersleben, it is their relation that is diseased; of the body to the mind, so that perception is morbid; of the mind to the body, so that volition is disordered. From which, then, does that disturbed relation proceed, which, when established, becomes reciprocal? If from the organism, it is a physical disease; if from the mind, a mental one, although in a sense not to be defined. Were I to dogmatize to you on this abstruse matter, I would say that there are two kinds of insanity, one a mental disease, the other a bodily one, both acquiring the psychosomatic character. There is a form of insanity produced by mental causes, in which the physical symptoms appear secondarily, which is sometimes curable by moral means, and which, if uncured, either leaves no traces behind, or a morbid anatomy which is its result, and in no case its cause.

The other form proceeds from physical derangement, occasions sympathetic mental aberration disappearing with its cause and having a traceable pathology.

Of the allied conditions of which I have been speaking, hallucination, stupidity, eccentricity, excited fancy, and moral obliquity, would range with the former; and illusion, hypochondriasis, and hysteria, with the latter. But the essential state—the diseased reciprocal relation disturbing personality—would be fully represented only by those conditions which I have now omitted to enumerate—namely, delirium and dreaming. The others have a resemblance to insanity in their origin, but do not partake of its essential character.

I repeat, that insanity is not, strictly speaking, to be termed either a bodily or a mental disease; that it is a disturbed reciprocal relation of mind and body; but that in its origin it is sometimes a mental, sometimes a bodily disorder; and that in the allied states alluded to, sympathetic delirium—which, if we recognize the two kinds of insanity spoken of—is a representative of the second, and the delirium of dreaming, which is a representative of the first, are the only conditions that have the same essential nature with what is termed unsoundness of mind.

Original Communications.

BRIEF NOTES ON THE DISEASE, INDIAN VILLAGE CHOLERA, AND ITS TREATMENT.

By ASSISTANT-SURGEON MOORE, B.A.
Gwalior Contingent.

[Continued from last vol. p. 1107.]

PART V.

Treatment.—Emeticised antimonial powder,* prescribed in doses of from five to ten grains, after the lunar caustic has made an impression on the morbid inflammatory action in the stomach and intestinal canal, will in general effect a diversion of the sero-mucous secretions from the gastro-intestinal mucous membrane to the skin. The functions of the kidneys have also been restored. The first discharge of urine from the bladder has flowed in a turbid

stream, and has been loaded with a thick sediment. In the subsequent treatment, strict attention must be paid to supplying the patient with light nutritious food, and in regulating the bowels by mild purgatives. By degrees the inspissated and tenaciously-adherent mucus becomes detached from the surface of the mucous membrane, and forms the bulk of the dejections passed from the bowels. The stools are ashen-grey in colour: at a later period they become tinged with bile.

The General Board of Health in London have favoured the public and the profession with important notifications relative to the measures to be adopted in the premonitory stage of cholera. The following paragraphs have been extracted from one of these notifications:—

“Cholera!—Medical authorities are agreed, that the remedies proper for the premonitory symptoms are the same as those found efficacious in common diarrhoea; that the most simple remedies will suffice, if given on the first manifestation of this symptom; and that the following, which are within the reach and management of every one, may be regarded as among the most useful: namely—20 grains of opiate confection, mixed with two table-spoonfuls of peppermint water, or with a little weak brandy and water, and repeated every three or four hours, or oftener, if the attack is severe; or an ounce of the compound chalk mixture, with 10 or 15 drops of laudanum, repeated in the same manner: from half a drachm to one drachm of tincture of catechu may be added to this last *if the attack is severe*.

“Half these quantities should be given to young persons under 15, and still smaller doses to infants, &c.

“(Signed)

CARLYLE.

E. CHADWICK,
S. SMITH.”

Cholera must be a disease simple in its form, and mild in its symptoms, when it yields so readily to these, the simplest of remedies. What explanation can the members of the General Board of Health give, for 12,000 persons of all ages, male and female, having been swept away, in the course of six or eight weeks, in Great Britain alone? What explanation can the noble Earl, the President of the Board, and his colleagues, give, when the victims of

* Vide MED. GAZ.—Antimonial Powder, 100 grains; Tartar Emetic, 5 grains: rub together.

cholera lie numbered not by hundreds, but by thousands, in an island where opiate confection and weak brandy and water,—where compound chalk-mixture, laudanum, and tincture of catechu,—such efficacious medicines in subduing cholera in its early stages, were within the reach of every one? The rates of mortality prove too clearly that they have erred in opinion. The same rates prove too clearly that the public has been misled by the representations of the members of the General Board of Health. The harmonious agreement of opinion among medical authorities, proclaimed by the General Board of Health, is in reality the harmony of discord. The unanimity of opinion as to the treatment to be adopted in cholera, is the unanimity of antagonistic conflicting opinions. The unheard-of discovery made by the noble Earl and his medical colleagues is worthy of being recorded in the medical literature of Great Britain.

In all discharges from the bowels—serous, mucous, or sanguineous; sero-mucous, muco-sanguineous, or sero-muco-sanguineous; whether such be designated by nosologists as acute or sub-acute diarrhoea, acute or subacute dysentery, acute, or mild English, or Asiatic cholera—there is no plan of treatment which will bear comparison with the extensive abstraction of blood, by cupping, from the surface of the abdomen, and the action of lunar caustic brought into immediate contact with the surface of the inflamed and secreting mucous membrane.

CASE XXI.—Bhola Naick, 4th Company, 5th Infantry, Gwalior Contingent, was sent in from the out-station of Balahut, in the district of Chundeeree, on the 22nd November, 1849. He had been seized with violent purging on the morning of the 21st. On admission into the Regimental Hospital at Lullutpoor, the discharges from the bowels were clear and sero-mucous in appearance, mixed with flakes of lymph, and containing a thick sediment. He was sunk and exhausted. The skin of his face was pinched backwards, giving a sharp and peculiar cast to his features. Thirst was urgent. The pulse ranged between 120 and 125, and was small, sharp, and wiry. The extremities were cold; the abdomen was sunken. The number of stools passed since the attack were stated

by him to have been twenty-eight or thirty. Within an hour after his arrival four liquid stools were passed. He did not suffer from vomiting, nor from spasmodic contractions of the muscles.

The treatment adopted consisted of cupping over the surface of the abdomen, and the administration of caustic pill No. 3. The cupping was succeeded by the application of a blister, which was afterwards dressed with mercurial ointment. A second pill was ordered, and with each pill as much cold water as the patient could drink.

“The sero-mucous secretions from the bowels were checked; thirst was allayed; the pulse fell to 90, and expanded in volume; heat returned to the extremities; the absorption of the mercury into the system was quick and unexpected; the gums became spongy, and the breath fetid. Beyond this the mercurial action was not pushed. As the bowels were not moved, except by the aid of a mild purgative draught, he was pronounced convalescent on the fourth day after admission.

CASE XXII.—Sawut Sing, Sepoy, 6th Company, 5th Infantry, Gwalior Contingent, was admitted into hospital at Lullutpoor, on the 5th November, 1849, having been purged twelve times previous to his removal. The discharges from the bowels were thin, sero-mucous, and mixed with blood. The pulse was quick, small, and wiry, 180 in the minute; the tongue was red. He suffered from thirst. The extremities were cold; the abdomen was sunken. He was so completely exhausted that with difficulty he spoke. The voice was feeble. He did not suffer from vomiting, nor from cramps, nor from suppression of urine.

He was cupped extensively over the abdomen; blood flowed freely. Caustic pill No. 3 was washed down with a quart or more of cold water given at short intervals. The pill was repeated in the evening.

After the first pill he had four liquid discharges from the bowels, tinged with blood. On this account the pill was repeated. After the second caustic pill the discharges were checked. The bowels did not act until a purgative draught was prescribed. The pulse fell to 96, and expanded in volume. Heat returned to the extremities. His recovery was satisfactory.

ABSTRACT OF CASES OF SEROUS, MUCOUS, AND BANGUINOUS DISCHARGES FROM THE INTESTINAL CANAL, TREATED BY CUPPING EXTERNALLY, AND LUNAR CAUSTIC INTERNALLY.

Names and Ages.	Date of Attack.	Character and number of liquid discharges from the intestinal canal.	Chief symptoms attending the discharges from the bowels.	Treatment.	Results of treatment. Effects produced on the symptoms and state of the bowels.	GENERAL REMARKS.
Case 23. Bahadur Sing, Sepoy, 1st Co. 5th Infantry. Gwalior Contingent.	Admitted, with symptoms of fever, on 5th Nov. 1849. On the 7th violent purging set in.	Nine liquid discharges in the course of 12 hours—sero-mucous and deeply tinged with blood.	Thirst urgent. Pulse 120, small, contracted, wiry; tongue red and glazed. Burning heat of skin. Pain in the abdomen; gripping. Restless and anxious.	Cupping extensively over the abdomen. Lunar caustic pill No. 3 washed down with copious draughts of cold water, or warm water if preferred.	One sero-mucous discharge in the course of 24 hours, free from blood. Pulse fallen from 120 to 89, full and soft. Thirst allayed. No return of the slimy discharges from the bowels.	At the onset of the purging a rhubarb draught, with ipecacuanha, was given. This was followed by blue pill and Dover's powder. The discharges from the bowels, however, increased in quantity and in frequency. The treatment was then changed. He was discharged convalescent on the 11th.
Case 24. Lehahat Khan Sower, 1st Troop, 1st Cavalry. Gwalior Contingent.	18th Nov. 1848.	Nineteen copious, liquid, muco-sanguineous stools in 24 hours. Colour deeply dyed of a blood-red. Flakes of lymph and shreds of mucus floated in the fluid.	Extreme exhaustion. Pulse less. Spasmodic twitches in the muscles. Thirst insatiable. Eyes sunken in their sockets. Extremities cold. Skin of the fingers and toes shrivelled. Urine not suppressed.	Cupping Cautic pill No. 3 to be repeated. Blister to the abdomen, to be dressed with mercurial ointment.	Discharges checked, and the cramps relieved. On the 14th, two liquid stools, slightly tinged with blood, were passed. On the 15th, none. On the 16th, none. The pulse returned. A warm perspiration broke out over the body.	After the second gush of muco-sanguineous fluid, he was ordered 5 grs. of calomel, and 4 grain of opium, every 3rd hour. He swallowed 4 pills. A mustard cataplasim was applied over the stomach. The discharges from the bowels, rapidly increased. After the 19th stool, the treatment was changed. The mercury was rapidly absorbed into the system by the raw blistered surface. The gums became spongy. The breath fetid, and salivation followed.

Case 25 Umur Anesty, Sepoy 6th Company, 5th Infantry, Gwalior Contingent.	15th Nov. 1849.	Ten liquid sero-mucous discharges from the bowels in the 24 hours, mixed with flakes of lymph, and a muddy deposit in the pan for five consecutive days.	Pulse 100, hard, sharp, and wiry. Thirst urgent. Anxiety. Prostration of strength. Gripping and tenemus. Tongue red and glazed.	Cupping over the abdomen. Caustic pill No. 3 morning and evening. Hot or cold drinks to be supplied when desired by the patient.	Frequency of the discharges diminished from 10 to 3, after the 3rd. and 17th, blue pill and Dover's powders were ordered. No impression was made on the state of the bowels. The treatment was changed. The pulse fell to 84, and expanded in volume. A perspiration broke out all over the body. He was discharged convalescent.	When taken to the hospital he received a rubarb draught, with laudanum. On the 16th and 17th, blue pill and Dover's powders were ordered. No impression was made on the state of the bowels. The treatment was changed. The pulse fell to 84, and expanded in volume. A perspiration broke out all over the body. He was discharged convalescent.
Case 26. Mattra Tewarry, Sepoy, 2nd Company, 5th Infantry, Gwalior Contingent.	24th Oct. 1849.	The complaint commenced with 5 stools in the day, and 6 in the night. On the 24th 12 liquid slimy stools were voided in the course of 12 hours. They were tinged with blood, and loaded with flakes of lymph and an ashen-grey coloured sediment.	Thirst insatiable. Restlessness. Anxiety. Prostration of strength. No appetite. Urine scanty, and high coloured. Pulse 124, small and thrilling. Tongue loaded and clammy.	On the 26th he was cupped over the abdomen, and was ordered caustic pill No. 3, to be washed down with large draughts of cold water.	In the 24 hours preceding the cupping, 13 copious sero-mucous stools were passed from the bowels. From the 26th to the 28th, after the caustic pill the bowels were moved once.	A rubarb draught, with laudanum, blue pill, and Dover's powder, with astringents, were tried in the first instance. They failed in checking the purging. The results of cupping and lunar caustic were so far satisfactory that the Sepoy was discharged from the hospital, at his own request, on the 29th Nov. 1849.
Case 27. Ajoodha Sipahi, 3rd Company, 5th Infantry, Gwalior Contingent.	22nd Oct. 1849.	Complaint ushered in by 7 stools in the day, and 6 in the night. On the 23rd, 6 in the day, and 11 in the night; total, 17 liquid stools in the 24 hours. Sero-mucous, and of a reddish tinge.	Thirst moderate. Gripping and tenemus. Quick and wiry pulse. Restless and anxious. Loaded and clammy tongue.	On the 24th, was cupped; and was ordered caustic pill No. 3.	In the 24 hours preceding the cupping and pills, 17 liquid evacuations were passed. From the 24th to the 26th, one discharge of a sero-mucous character was voided.	The astringents employed to check the purging failed. The irritability of the bowels increased on the 23rd. The plan of treatment was changed. The results arising from the cupping and caustic pills were so far satisfactory, that "convalescent" was written opposite his name on the 26th November, 1849.

ABSTRACT OF CASES—continued.

Name and Age.	Date of Attack.	Character and number of liquid discharges from the intestinal canal.	Chief symptoms attending the discharges from the bowels.	Treatment.	Results of treatment.—Effects produced on the symptoms and state of the bowels.	GENERAL REMARKS.
Case 28. Ram Sing, 25 years. Regiment.	20th Sept. 1849.	Profuse alimy, sero-mucous stools, passed 20 times in the 24 hours. Examined with the aid of a lens, lymph and mucus, in considerable quantity, were noticed.	Prostration. Heat of skin. Foul tongue; thirst; restlessness and general fever. Pulse 110, throbbing. Pain in the iliac regions. Scanty and high-coloured urine.	Cupping. Lunar caustic pill No. 3, morning and evening.	Cessation of the violent purging after the 2nd pill. Pulse reduced to 80, soft. Perspiration over the body. Copious flow of urine.	Without wasting time, and trilling with the symptoms, by administering laudanum, &c. this man was cupped, and had the caustic pill. He returned to his village on the 3rd day.
Case 29 Jánari Pundit, prisoner. 60 years.	20th Nov. 1849.	Looseness of the bowels; three thin alimy discharges in the night, and thirteen in the day. Liquid passed the same as in Case 28.	Furred tongue; quick pulse. Thirst urgent. Pain and griping in the bowels. Scanty urine, high-coloured, but not suppressed.	On the 24th 1 caustic pill No. 3. On the 4th Dec. cupped and ordered caustic pills morning and evening, blistered.	The number of stools was reduced to 1 in the 24 hrs. From the 26th to the 30th the bowels were not moved once. On the 4th December purging returned, which called for the treatment noted.	From the 20th to the 24th Nov the treatment consisted of opiates and astringents. The caustic pill was substituted when the purging continued. For four days the bowels remained totally inactive. The return of the sero-mucous stools, rendered it necessary to cup and blister. Recovery soon followed.
Case 30. Jabra Senar, prisoner. 30 years.	28th Nov. 1849.	Seven stools in the day and 5 in the night: thin alimy, sero-mucous, and deeply tinged with blood. Flakes of lymph and shreds of mucus in considerable quantity.	Thirst insatiable. Dry and crisp tongue, glazed. Small and thready pulses, 126 to 180. Punched features; cold extremities. Griping pains in the abdomen. Urine secreted.	Cupped extensively, caustic pill, No. 3. Blistered, and dressed with mercurial ointment.	The evacuations reduced from 18 to one. This was passed on the morning of the 30th Nov. In the evening, a second evacuation, more healthy in colour and consistence, and free from blood, was passed. The pulse fell to 90.	No delay took place in the remedial measures employed. This prisoner was cupped at once, and was given the caustic pill, with large draughts of cold water. He was then blistered. Mercurial action set in on the 8th of December. His recovery was satisfactory.

The cases registered in the foregoing table may be classified as cases of diarrhoea or of dysentery; of choleraic diarrhoea, of cholera mitis, or of cholera Asiatica atrocissima, by those who cannot recognise nor prescribe for a disease except it possess a specific name. It is high time that medical men should prescribe for the diseased structures from whence arises a specific train of symptoms, and not trifle with disease in adapting medical treatment to the fine-drawn distinctions between the morbid conditions of the same structure, denoted by specific euphonistic names.

The serous, mucous, and sanguineous, —the sero-mucous, muco-sanguineous, and sero-muco-sanguineous discharges of fluid from the intestinal canal, mixed with flakes of lymph and with shreds of inspissated mucus, could not have been voided unless there had existed a fretted, an irritable, an inflamed condition of the whole, or of some one part of the gastro-intestinal mucous membrane, glandular bodies, and subjacent tissues. This is the point which must be borne in mind. The extent of mucous surface engaged constitutes the sole difference between diseases closely allied, which may be ranked in one and the same family. The limited extent of surface from whence the sero-mucous discharges were eliminated, rendered the cases recorded tractable to treatment.

The first gush of sero-mucous fluid from the stomach and intestinal canal has been called the premonitory diarrhoea of cholera: this is an error. The members of the General Board of Health in London have fallen into this mistake in their notification on the subject of cholera. If it can be proved that a few inches of the intestinal canal above and below the *cæcum caput coli*, involved in a fretted, and irritable, and sero-mucous eliminating condition of its structures, is the point of departure for the spread of an extensively diffused inflammatory action upwards towards the stomach, and downwards towards the rectum, then may diarrhoea be regarded as the forerunner of cholera.

This theory will not stand the test of examination. The first gush of rice-water fluid from the stomach, and the first gush of rice-water fluid from the bowels, may be regarded, not as the *avant courier* of an attack of cholera, but as the *transit of the first into the second stage of the disease*, and originate in the rapid, the almost instantaneous develop-

ment, of a bright scarlet, or deep crimson red efflorescence, diffused over the internal surface of the stomach, the duodenum, the jejunum and the ileum intestines.

The premonitory diarrhoea,—with which the noble lord the Earl of Carlisle, President of the General Board of Health, and his medical colleagues, Mr. Ghadwick and Dr. Smith, appear to have been fascinated,—bears to the first and second stages of cholera as strong a degree of relationship as the flame of a farthing rushlight bears to the fiery blaze of a potter's furnace.

To extinguish that blaze they propose to add fuel to the fire.

[To be continued.]

CHLOROFORM IN A CASE OF POISONING BY STRYCHNINE. BY DR. MUNSON.

MR. G—, aged about 40, of intemperate habits, took from among some medicines, on the 5th instant, a bottle of strychnine; and supposing it to be morphine, as he said, swallowed a dose supposed to be about one or two grains. In about twenty minutes afterwards Dr. Munson was requested to see him, as he was supposed to be in a "fit." He found him in the following condition:—The whole muscular system rigid; the muscles of the back, and of the upper and lower extremities, rigidly contracted; the head drawn back; articulation difficult; sense of tightness about the chest, perspiration flowing profusely from the face and chest. A number of the physicians of the place came to his assistance. The usual remedies recommended in such cases were resorted to, but without any mitigation of the urgent symptoms. The patient was failing rapidly under the increasing spasmodic action of the whole muscular system. It was now determined to administer chloroform, as death was apparently certain without some relief. One drachm of chloroform was put upon a silk handkerchief, and the patient directed to inhale it. The effect was decisive. The patient (who was at this time in a sitting posture, held so by assistants, who could not move him in the least degree without exciting the most frightful and alarming spasms) requested to be placed in a recumbent position, which was done without exciting the least spasm. The chloroform was carefully administered for some hours, the patient holding the handkerchief most of the time himself, in order, as he said, "to keep off the dreadful spasms." From this time he recovered rapidly, and on the 7th instant was able to leave for home—a distance of six or seven miles.—*Doctrs Medical Journal*, July.

SCROFULA IN ITS RELATIONS TO
PULMONARY PHTHISIS.

(OKALATE OF LIME IN THE URINE.)

By THOS. BALMAN, M.R.C.S., L.A.C., &c.
Hon. Surgeon to the St. Anne's Dispensary.

ABOUT twelve months ago I suggested to one of my colleagues that each of the honorary surgeons of the Dispensary should be at liberty to select some particular group or class of diseases as his speciality, and that the cases belonging to such group occurring in the practice of the other surgeons should, as far as might be agreeable, be transferred to the care of the surgeon who had adopted this particular speciality. In this request all my colleagues readily acquiesced: hence the origin of the present paper. To my colleagues,—Messrs. Nottingham, Padley, Taylor, and Harris,—therefore, I am indebted for the opportunity thus afforded me of seeing and treating a larger number of cases, embracing almost every form and variety of the scrofulous disease, than could have fallen to the lot of many other individuals under the most favourable circumstances. The plan I set out with, and which I have steadily pursued up to this time, has been to note down the particulars of each case in the following order:—

1. Everything relating to the age, sex, precise form and duration of the disease, together with any external peculiarity in any way worthy of notice. 2d. The diseases that appeared the most frequently to have prevailed in the family, as regards brothers and sisters, parents, their brothers and sisters, separating each family under two heads,—viz., the number living, and if healthy or otherwise; and the number of deaths, and the causes thereof. Lastly, the grand parents on each side. From information obtained in this way have been collected together the particulars of 100 cases. This might appear at first sight a very easy task, but in reality it is not so; and is due in part to the ignorance of a large class of persons who seek relief at a dispensary rendering them unable, if willing, to furnish the necessary information, and also to the circumstance that in a mercantile town like Liverpool the relations of the person are very often scattered over almost every part of the globe: and, therefore, anything like a connect-

ing link in the family, as regards their state of health, physical or otherwise, it would be quite impossible to establish. With these and many other almost insuperable difficulties with which such an investigation is beset at its very threshold, no alternative was left but to pass them by as useless for any special statistical inquiry; otherwise I could, with much less labour, have troubled the number of cases now recorded: added to which, I have confined myself to one individual symptom, for reasons presently to be stated, by which I choose to identify the disease—viz., those affected with enlarged cervical glands of at least two months' standing, excluding all those cases in which such swellings appeared in any way to have arisen from other causes than the scrofulous taint; such, for example, as the sympathetic glandular tumors, as a consequence of any irritation of the scalp, painful dentition in children, and all other sources calculated to throw any doubt as to the diagnosis of the case.

Tumid absorbent glands of the neck have been selected as a diagnostic symptom, because such indication has been looked upon by almost every writer, from the earliest periods, as the characteristic type of the disease. Abnormal deviations of many other tissues, though generally regarded as due to scrofula, might not be considered by every one as belonging to this particular catalogue.

From these 100 cases I have endeavoured to tabulate all the more important features of each case, so as to present almost at a glance an epitome of the whole. The second table shows a large relative proportion of cases between the ages of 2 and 15, which can hardly be considered as giving a fair average, since about a third of the whole of these cases were obtained from children of both sexes attending some of the national schools of this town.

Table 5 has appeared to me especially interesting in connection with the etiology of scrofula, bearing as it does upon a subject on which the profession appear to be somewhat divided. The existence of phthisis in the family of so large a proportion of scrofulous individuals must be regarded as one of the strongest external proofs that can be adduced in favour of the identity of the two diseases.

It is perhaps hardly necessary to mention that these numerical statements

can only be regarded as a very close approximation to truth, and must apply equally to every investigation having similar objects in view; but I have every reason to believe that they will be found to be as perfect, as far as they go, as they can well be made. In all cases where it was possible, the information was obtained from the parents. When under age, or disqualified in any way from furnishing what I considered to be a correct statement, and when there appeared to be the least reason for questioning the veracity of my informants, the case was invariably laid aside.

TABLE I.

Showing the relative number of persons affected with Scrofula, as regards Temperament, &c.

	Male.	Female.	Total.
Number having light hair and complexions . . .	31	15	46
Do. having dark hair and complexions . .	22	13	35
Do. having red hair	12	7	19
			100
Do. presenting what is commonly known as the scrofulous countenance. . .	21	6	27

The results, on the whole, go to show that scrofula is for the most part common alike to all temperaments.

TABLE II.

Showing the proportions affected with Scrofula at Different Ages.

	Male.	Female.	Total.
Number affected with scrofula from 2 to 15 years of age . .	52	27	79
Do. from 15 to 30	11	8	19
Do. 30 and upwards	1	1	2
			100

The numbers in the first column will probably exceed the average, from the circumstances already alluded to.

TABLE III.

Showing the frequency with which other regions are affected with Indurated Scrofulous Glands simultaneously with those of the neck.

	Male.	Female.	Total.
Number of cases in which the neck only was affected . . .	56	38	89
Do. neck and axilla	4	1	5
Do. neck and popliteal space . .	1		1
Do. above the bend of the elbow	2	3	5
			100

The fourth column refers to cases in which a lymphatic gland, always found a few inches above the inner condyle of the humerus, was enlarged, or presented other characteristic indications of being the result of a scrofulous taint. I found the groin affected in two cases only.

TABLE IV.

Showing the probable Exciting Causes of Scrofula.

	Male.	Female.	Total.
Measles, scarlatina, and whooping-cough . .	19	12	31
Exposure to cold or damp	3	3	6
Cause not evident	38	20	58
Blows and other external injuries	1	1	2
Syphilis	2	1	3
			100

Of the causes mentioned in the first column, by far the most frequent appeared to be measles, terminating in a profuse catarrhal discharge from the mucous surfaces of the eyes, nose, and ears: on the cessation of this discharge the glands of the neck became tumid. I have notes of many cases in which diarrhoea, disconnected with the above, seems to have preceded the first manifestation of the disease. These lumps or kernels, as they are vulgarly called,

may continue for a longer or shorter time,—may return in the spring of each succeeding year, to disappear during the progress of summer, or remain stationary, sometimes pertinaciously resisting every therapeutic means employed for their removal until the age of puberty, when these swellings may vanish completely, and the person attain an advanced age, and ultimately die of some other complaint; or, what I believe to be not uncommon, perish of pulmonary phthisis in the first epoch of manhood.

In connection with the fifth column, I have some particulars of five other cases (males) in which the venereal taint had undoubtedly been the exciting cause, making seven cases in the whole. They are not included in the list because their history could not be ascertained: but, as far as my inquiries extended, there had been in every instance a phthisical tendency either in the parents or collateral relations. In six out of the seven cases, the sores appeared to have assumed a phagedenic character, attended with phimosis.

If a given number of well-recorded cases could be found in which scrofula manifestly appeared for the first time after a true syphilitic sore, without any predisposition to tubercular disease in any part of the family, such a circumstance would, I imagine, be a strong argument in favour of the occasional syphilitic origin of scrofula. The glands of the neck became affected about the same period after the primary sore as constitutional syphilis usually appears—viz., from the sixth week to the third month; and slight symptoms of the latter sometimes co-existed.

Mercury appears to have been injudiciously administered in almost every instance.

This class of persons are benefited in a very marked way by the internal use of iodide of potassium, all other reputed scrofulous remedies proving of no service whatever.

The following table exhibits the number of instances in which one or more deaths from consumption occurred in the family of each respective person having the fore-mentioned symptoms of scrofula. The aggregate number of deaths in each family are not stated, because it might tend to confuse the reader without adding much weight to the argument. It would have been

more complete if the causes of death, as regards the brothers and sisters of each grand parent, had been added: that was my intention, had I not afterwards found the extension of the inquiry to these branches to be impracticable.

TABLE V.

Showing the number of instances in which deaths from phthisis occurred in the families of 100 cases of scrofula:—

Own or patient's brothers and sisters.	Father.	Mother.	Number of families on the parents' side in which have been one or more cases of phthisis.	
			Male.	Female.
6	6	7	42	32

TABLE VI.

Showing the number of cases in which Phthisis appears to have been transmitted to their immediate issue:—

On the Father's side.

In the 100 cases of scrofula, phthisis is traced as above in 88 instances, leaving only 17 in which no deaths from that disease could be ascertained. The sixth table, though on a small scale, is of sufficient interest to be appended to the above, bearing as it does directly upon the hereditary predisposition to phthisis, and the proportion of cases in which the disease seems to be inherited respectively from the phthisical parents, male and female. Thus the disease appears transmitted by the father to his issue in seven instances, and not in five; by the mother in four instances, and not in eight, and so on. It follows, therefore, that the phthisical father more frequently transmits the disease to the offspring than the mother, in the ratio of 7 to 3; whilst on the mother's side the ratio is as 6 are to 7.

TABLE VII.

Shows the number of deaths from other diseases in parents and grand-parents, some of which have been supposed to be sometimes associated with the scrofulous constitution: the former are classed together:—

	Parents.	Grand-parents (male).	Grand-parents (female).	Total.
Nervous system, including apoplexy or paralysis, mania, and epilepsy	5	12	7	24
Cancer	1	—	5	6
Calcul. Comp.	—	2	—	2
Cholera	1	2	5	8

It is not an easy matter to determine, with any degree of accuracy, the previous existence of scrofula in the parents and collateral relations in a sufficient number of cases to warrant one forming any very satisfactory conclusions. A person, for example, may have had the lymphatic glands enlarged from a scrofulous taint in early life, and afterwards disappeared without attracting any particular attention. Again, scrofulous disease of the joints, caries, rickets, and such analogous affections, though commonly recognised as belonging to the scrofulous constitution, are but imperfectly understood by unprofessional people. Any injury of this kind must, I conceive, be on this account more or less imperfect. The following results are therefore submitted from my notes, without wishing to insist very strongly on their value:—In 30 per cent. of the cases examined, scrofula appears to have shown itself in one or more of the brothers and sisters; in 11 per cent. in the parents, and 9 per cent. in the grand-parents.

Urine.—I have examined the urine in thirty-two cases. The specimens brought me were generally observed to be of a pale amber colour, perfectly transparent, and deposited, on standing, only a very light filmy sediment. Occasionally, however, it was turbid from an excess of urates. The specific gravity ranged from between 1·005 and 1·030, the average being from 1·012 to 1·020. As a rule it was acid, rather

more weakly than in the healthy condition; and in two instances it was neutral to the blue litmus paper. It had often a strong odour of cod-liver oil, in cases where this medicine had been taken for any length of time. In two instances the urine appeared turbid, from containing oil-globules of some sort; at least, this was my impression on viewing under the microscope a minute portion of the densely connected cloud of this substance that appeared floating almost entirely on the surface of the liquid.

In considerably more than half of these cases—nineteen out of the thirty-two—I found, by microscopical examination, octohedral crystals of the oxalate of lime. In ten instances the oxalates were so abundant that, on placing a few drops, taken from any portion of the liquid, in a small glass cell under the microscope, and with a $\frac{1}{4}$ or $\frac{1}{2}$ inch* object-glass, the field seemed literally covered with large well-defined crystals. In the remaining nine specimens the oxalates were fewer in number, smaller, and not so easily recognised, though quite distinct when carefully examined. In two instances I failed to detect them until the urine had been concentrated by heat, when they were immediately visible in tolerably large numbers. The average specific gravity of the urine containing the oxalate of lime was from 1·018 to 1·025. In one case it was lower than I have found it in any other instance, viz. 1·005. The urine was generally of a pale, transparent, amber colour, seldom turbid. On allowing the former to stand a little time, a delicate cloud seemed to remain diffused through the liquid for a considerable time without falling to the bottom of the vessel. This appeared to me quite characteristic, and agrees, as Dr. Golding Bird has stated, from the oxalates being about the same specific gravity as the urine. Three of the specimens exhibited traces of albumen by the usual tests; and twice the crystals appeared marked by an excess of square and cylindrical-shaped crystals of uric acid, as, on the addition of a drop of liquor potassæ, the latter immediately disappeared, and brought the oxalates very beautifully into view. In no instance did there appear to be an excess of phosphates in combination with the oxalate of lime.

In the thirteen specimens in which the oxalates were not observed after the most careful examination, I find there are four in which the phosphates were in excess,—that is, the liquid was rendered distinctly turbid by heat, which turbidity was removed by nitric acid. Two were specimens of the urine obtained from persons with well-marked cases of tumid glands of considerable standing, where the exciting cause had clearly been venereal.

This class of cases must not, however, be considered as exceptional; for it is well known that the oxalate of lime has been very often noticed in connection with some of the more inveterate forms of syphilis: and one of the finest specimens I have observed occurred in a young man of 22 years of age, who presented one of the most disgusting cases of scrofulous disease, affecting the whole anterior part of the neck and axilla,—caused, no doubt, in a great measure, by the injudicious use of mercurial medicines.

Two were cases where the cervical glands had suppurated, and were rapidly cicatrizing; leaving five cases in which the lymphatic glands were in a more or less state of congestion or disorganization, in all probability from a scrofulous taint, without the urine exhibiting any traces of the oxalate of lime after the most careful examination. A question of a very interesting nature here presents itself to my mind—Has the presence of the oxalate of lime, which we have observed so frequently in the urine, or that condition of system, whatever it may be, by which it is formed, and afterwards separated by the kidneys, any connection with the origin, growth, and unusually lengthened persistence of these scrofulous tumors; or is the occurrence of this substance foreign to the healthy economy, accidental, or due to any particular system of diet, or otherwise? Before this question can be fairly met, a much more extended series of observations will be necessary than those now presented. If, for example, the oxalates should be found to appear in the urine simultaneously with the first manifestation of the swelling, and continue as long as any degree of activity is displayed in the gland, and finally disappear upon the subsidence of these tumors, a strong argument as to their mutual relationship might be esta-

blished. Without indulging in any speculations on this subject, without a sufficient number of well-attested facts to guide me, I will simply add, that it is possible that the oxalate of lime may more frequently occur in the urine in other diseases than is commonly believed; and perhaps, occasionally even, in minute quantities, in a comparatively healthy state of system.*

Treatment.—Most persons, I think, will admit that the treatment of these cases is, in the majority of instances, anything but satisfactory: hence the unfortunate sufferers too often become the prey of unprincipled charlatans and ignorant pretenders of every grade.

The difficulties with which these cases are surrounded are due to impaired nutrition of the system generally, and likewise to the anatomical structure of the organs locally affected. Unless we can succeed in arresting the deposit of tuberculous matter, which gradually destroys the gland, and with it the tissue by which it is more immediately invested (hence the burrowing of the matter in the adjoining cellular membranes causing sinuses and loss of substance very difficult to be replaced in the scrofulous habit), this disease must always remain tedious and harassing to the practitioner. Much relating to the treatment of scrofula, as affecting the lymphatic glands in their different stages of development and decay, I propose to make the subject of a more special inquiry at some future period. In the meantime I may state that, as regards internal remedies, I have found more benefit from the dilute phosphoric acid, given in some bitter infusion, such as Columbo, than any other medicine. Iodine in all its forms has, I believe, been much over-estimated; and cod-liver oil, so much vaunted of late, though of much service in scrofulous affections of the osseous tissues, has not appeared to manifest any very marked effects in this peculiar form of the disease.

I am indebted to Dr. Brett, whose contributions on the subject of urinary sediments will be familiar to the readers of this journal, for kindly examining many specimens of the urine with me, and otherwise affording me much valuable aid.

* When this was written I was unacquainted with the observations of Dr. B. Jones on this subject, recorded in the *Lancet* for Feb. 9, 1850.

I ought likewise to express my obligations to Dr. Drysdale, for throwing in my way many very interesting cases.

ON THE CONTAINING-TEXTURE OF THE BLOOD.

By WILLIAM ADDISON, M.D. F.R.S. F.L.S.

THE relations which have been established between the process of repair and inflammation, and between these and natural growth, have invested embryological researches with a new interest, especially with reference to the development, properties, and transformations of vascular tissue, or, as it may be more suggestively expressed, *the containing-texture of the blood*. In the primitive trace of growth in the embryo, sentient and motor forms (spinal cord, cerebral ganglia, and heart) are the first moulded, and visible, through a lens, in the incubated egg of the common fowl within the space of forty hours. At this early period there is neither a blood-circulation nor blood vessels. Blood is first seen, not in the embryo-body itself, but in the vascular area, where it primarily appears in irregular, and apparently unconnected red points or blotches, which, when examined with a microscope, are observed to be groups of red cells situated amongst the other cells of this embryonic appendage, and no special limiting or boundary tissue can be distinguished. As growth advances, the amount of blood increases, circulation begins, and the coats of the vessels then become recognisable as a distinct form of tissue interposed between the blood-current and the fixed and more solid portions of the structure. This constitutes the coats of the arteries, veins, and capillaries, as distinguished from the particular substances of the various organs through which blood is distributed, and is, at first, in accordance with the universal law of growth, a corpuscular, and subsequently a fibrous tissue, increasing gradually in thickness and strength, in the arteries and veins, in proportion to the increase and volume of the blood conveyed; but in the capillaries remaining, as at first, exceedingly thin and transparent.

These facts are, we believe, not disputed, and they are here briefly nar-

rated in order to state the case:—That, in original growth, forms of sentient and motor tissue precede the circulation of the blood; that the circulation of blood precedes the formation of the special coats of the blood-vessels; and that these are at first a corpuscular, and then a fibrous texture.

Experiment 1.—Having opened the shell of an egg after forty or forty-four hours' incubation,—some eggs being earlier than others,—divide the yolk membrane with a pair of scissors all round, just outside the vascular area; then sink the egg slowly in a vessel of water, and the separated portion, which includes the *vascular area*, *area pellucida*, and the *embryo*, will float at the surface, and may be removed upon a slip of glass for microscopical inspection, either as an opaque, or as a transparent object. Blood is seen in the vascular area, in apparently unconnected, irregular, pale red spots, which are larger and more numerous towards the outer circumference than towards the inner margin, where the area vasculosa bounds the area pellucida. The area pellucida is formed by a thick gelatinous sort of membrane, in the centre of which lies the embryo, with the cerebral ganglion, the two lateral visual ganglia, and the spinal cord, symmetrically moulded. The heart appears as a round transparent vesicle, outside and towards the middle of the body, and has been seen beating regularly, notwithstanding the manipulation to which the embryo and its appendages have been subjected by the removal. No appearance of blood can be detected in any part of the embryo-body: certainly there are no blood-vessels, properly so-called; nor at this time can any capillaries be seen traversing the area pellucida. The whole mass is so extremely soft and tender, that it will not bear the slightest degree of traction.

Experiment 2.—The same proceedings being adopted with an egg of from forty eight to fifty-two hours' incubation, the trunks of two large blood-vessels are seen emerging, one on each side, from beneath the body of the embryo, some distance below the heart, and one from the heart passes upwards by the head. They traverse the area pellucida, and, reaching the inner margin of the area vasculosa, divide and sub-divide; then, the smaller sub-divisions returning

to the inner margin of the area vasculosa, numerous capillaries are seen passing across the area pellucida towards the body of the embryo (figs. 1 and 2). Blood-corpuscles are now seen circling

within the heart upon each pulsation; and others are at the same time also seen moving within those portions of the trunks of the vessels which traverse the area pellucida.

FIG. 1.

FIG. 2.

FIG. 1.—The embryo, area pellucida, and vascular area of the egg of the common fowl, after forty hours' incubation. Magnified by a lens.

FIG. 2.—The embryo, capillaries of the area pellucida, and vessels of the vascular area, after fifty hours' incubation. Magnified by a lens.

With respect to these vessels, a special blood-containing texture can scarcely yet be said to have formed, inasmuch as the blood-currents traversing the area pellucida are bounded only by the material of that membrane, which is quite transparent; and those ramifying in the area vasculosa are bounded by the material of that substance—the altered yolk-cells, and are therefore much more opaque. Moreover, the whole mass is still so soft and pulpy, that it will not bear the most gentle traction without obliteration, falling into a confused mass of cells; though it becomes more coherent after exposure to the air. This is not the character of vascular tissue. The correct anatomical description appears to be this (not only as respects the appendages of the embryo, but also as respects the embryo-body itself):—Whatever substance or texture blood first circulates in, the blood-channels are, for a brief space of time, formed or

bounded by that substance; so that, at first, no distinction can be observed between the coats of the blood-vessels and the substance lying in the intervals or spaces between them: whereas afterwards, when the body is more fully grown, and the volume of blood increased, a very important distinction arises between the containing-tissue of the blood, or the coats of the blood-vessels, and the *parenchyma*, or the particular substance of an organ. We cannot select a better illustration than the blood-vessels of the area vasculosa. The yolk of the egg consists of a very thin transparent membrane containing the yolk-cells. The germinal membrane is an altered state of the yolk membrane, and the vessels of the area vasculosa appear projecting into the yolk substance; so that, on their upper or *parietal* aspect, they are smooth and transparent, but, on their lower or *visceral* aspect, they are yellow and opaque. Three parts of their circum-

ference—that is, of their walls—are formed of cohering yolk-cells; the other part by the transparent and smooth yolk membrane.

In the increase and preservation of the human body we recognise three normal phenomena—growth, nutrition, and the process of repair; in its diseases, two prominent abnormal conditions—inflammation and scrofula. Respecting these we distinguish three things:—1, the blood; 2, the coats of the blood-vessels, or the containing texture of the blood; and 3, the particular substances of the different organs.

Of the blood we have on several previous occasions treated at length, especially with reference to its colourless elements—lymph and lymph-particles, or, as we have elsewhere more frequently termed them, protoplasm and colourless cells.* We now purpose to speak particularly of the containing-tissue of the blood—or, as we may more briefly term it, vascular tissue—with respect to the distinctive properties, reproduction, and transformations it exhibits in phenomena of repair, inflammation, and scrofulous disease.

The containing-tissue of the blood.—The coats of the blood-vessels, or vascular tissue, may be described as a sort of frame-work, in the interstices of which are deposited the various substances by which individual organs are characterised. It is these which impart the sensible qualities by which the organ is distinguished, and it is their constant and intimate admixture with the vascular tissue which prevents the special properties of the latter from being readily appreciable. In repair, inflammation, and scrofulous disease, we meet with new growth and new blood-vessels, the primary elements of which, all observers concur in stating to be forms of lymph and lymph-particles, capable of assuming, by a species of metamorphosis, a fibrous, tendinous, or osseous structure. A bone is composed not simply of bone-substance, but also of vascular tissue. Blood-vessels spread everywhere upon the bone-substance, which is full of hollow spaces and passages for their distribution. At the early periods of growth blood and vascular tissue predominate, and a bone

is therefore, at that time, soft and yielding; but afterwards the bone-substance preponderates,—yet so that a bone is never without an expanse of vascular tissue permeating its cavities. When a fracture occurs, the process of repair consists in the reproduction of bone-substance; and the agents and materials employed are blood and the vascular tissue of the injured bone.

The phenomena, for our present purpose, may be shortly stated as follows:

—Lymph is effused, forming a lymph-bed, which surrounds and envelopes the injured and irritated vessels; new blood-vessels form in the lymph, which is thereby converted into a species of lymph-fabric. This constitutes the primary form of the new vascular tissue,—a kind of granulation-structure, endowed with properties of growth and metamorphosis, and which, first changing into fibrous tissue, is finally converted into bone; the order of the transformations being here, and in all cases, lymph, vascular lymph or granulation-texture, fibrous texture, and bone.* Tendons consist of strong fibrous threads or cords, enveloped, and, as it were, bound together by vascular tissue. When a tendon has been ruptured, the process of repair appears, in all its primary stages, to be similar to that observed in bone. Effusion of lymph precedes the formation of new vascular tissue: analogously as in the embryo, the cells of the germinal membrane precede the vascular area. But here the transformations are limited to the fibrous type, not proceeding to the ulterior form of bone: and we readily perceive in this example, that whether the primary lymph-form persist, or whether the transformations exceed the natural fibrous form,—in either case the reparation of the tendon would be unnatural, and an abnormal or diseased condition would exist. The skin has a much more complex organisation than either a bone or tendon. It may be described as a web or frame-work of vascular tissue, in which are embedded, at variable depths from the surface, the particular substances of its very numerous perspiratory glands and hair-follicles. The phenomena of repair in the skin vary according to the nature and severity of the injury inflicted, or according as the before-mentioned

* MEDICAL GAZETTE, vols. i. and ii., 1840-41; Transactions of the Provincial Medical and Surgical Association, vols. xi. and xii.; and Provincial Journal.

* On Healthy and Diseased Structure, &c. 1840; also the Lectures on Repair by Mr. Paget.

organs embedded in it are more or less extensively and completely destroyed. The general results of scalds and burns, which exemplify phenomena of inflammation and repair, are well known. In the former, blood speedily accumulates, reddening the site of the injury, and phenomena of growth or nutrition are exaggerated. The cuticle is raised into a bladder filled with fibrinous serum, and lymph and lymph-particles form a new covering to the excited and distended vessels. These are succeeded by several layers of new cuticle, beneath which the vessels gradually resume their natural calibre and appearance, and the reparation is complete. In burns the injury is deeper, vascular tissue and its embedded organs being killed or destroyed. Hence a new growth of vascular tissue is required for reparation, the phenomena of which may be briefly summed up as follows:—At a certain depth from the surface vascular tissue regains its tone and properties, whereupon blood flows in increased quantity to the irritated vessels, lymph is effused, and thus a line of demarcation is drawn between the living and the dead textures. New blood-vessels form in the lymph, which thereby becomes new vascular tissue, endowed with properties of secretion and metamorphosis; and when, by the removal of the dead parts, this new vascular tissue comes into view, it is in the form of extremely red points, termed *granulations*, which bleed upon the slightest touch,—a fact indicative of the corpuscular or embryoniform condition of the coats of the new vessels. The granulations metamorphose into fibrous texture termed *cicatrix*, upon which *the cure*, in as far as natural operations are concerned, is completed. All these cases may be considered as examples typical of inflammation, repair, and cure: and it is to be observed that bone does not exude from bone, tendon from tendon, nor skin from skin; but that in each case a corpuscular growth, termed effusion of lymph, first appears. This, when permeated by blood-currents, becomes new vascular tissue, the metamorphosis of which effects the cure, whether that cure demand an osseous or a fibrous texture. Moreover, it is also to be observed,—at first, during the formation of new vascular tissue or granulations, that *the action is from the blood to the tissues*,—there is deposition,

or effusion, growth, secretion, and swelling: but subsequently, during the fibrous and osseous transformations, *the action is from the tissues to the blood*; these latter periods being marked by diminution of swelling, absorption, consolidation, a less amount of blood circulating in the part, and disappearance of a great many of the new vessels.

Respecting the relations subsisting between the lymph of repair and the lymph of the blood,—that is to say, between the colourless granular cells and protoplasm of new vascular tissue, and the colourless granular cells and protoplasm of the blood,—the following facts, which have elsewhere been discussed, may here be recapitulated:—Colourless cells are found in abundance in blood taken from vessels administering to repair or inflammation, and a delicate web of fibrous tissue may be seen with a microscope to form in the protoplasm or liquor sanguinis. The blood of the early embryo, when vascular tissue is in active growth, is scarcely more than lymph: the vessels of granulations are formed of lymph, and bleed upon the mere touch; and lymph and lymph particles adhere to the coats of the vessels upon irritating them. Moreover, when blood is withdrawn by venesection from a person labouring under an inflammatory disease, lymph separates quickly in a thick layer at the surface. This metamorphosis into a fibrous texture, the microscopical elements and physical properties of which appear to be of the same nature with these constituting the containing-tissue of the blood, or the coats of the blood-vessels, in the living body; allowance being made for the difference and disadvantage of the circumstances under which it is formed.

Lymph, lymph particles, fibrous tissue, and serous fluid, are thus demonstrably phases of blood elements, and the same elements are, more or less, components of vascular tissue. From these and other facts, which it is unnecessary here to recapitulate, we have derived the conclusion that *blood forms its own containing texture*; lymph, vascular lymph structures, and granulations, being the primary or proximate,—and fibrous, tendinous, and osseous textures, the more remote phases of the colourless elements of blood. Degraded lymph, and degraded forms of lymph texture, are termed pus, clots of pus, and tubercle.

or tubercular infiltration; persistent granulations are termed fungosities, fungous growth, or, in popular language, "proud flesh:" and it is these depraved and unnaturally persistent forms, together with the adventitious fibrous, tendinous, and osseous formations, arising from the metamorphosis of lymph and new vascular tissue, which constitute the diseased products of inflammation and scrofula. Ossification appears in the coats of the arteries, and *phlebolites* attached to the interior of the veins; inflamed mucous membranes discharge lymph and pus; and inflamed serous membranes assume the aspect of mucous textures, and then their surfaces become united, sometimes by soft lymph-structure, and sometimes by a dense fibrous tissue.* It does not seem necessary, in support of the conclusion we have drawn, to refer more largely to the organization of blood, or to the forms which its elements are capable of assuming, especially as numerous interesting facts may be found brought together in the lectures of Dr G. Burrows, from which we have just quoted. We therefore proceed to the other topic of our inquiry—the limitations of repair; for these appear to indicate the limits of the organization of blood, and explain the common characters of the products of inflammation.

It is well known that the extent and facility with which extreme injuries are repaired is directly as the age of the individual; so that in many of the lower classes of animals a whole limb may be removed at a very early period of life,

and be afterwards reproduced,—a phenomenon that does not happen when the full period of growth is more nearly completed. Now, in order to avoid difficult metaphysical questions, we may conveniently express the properties of growth in the embryo, when all the organs are evolving and expanding, by the term "*germ power*;" and say that, the younger the individual, the greater the proportion of unexpended or unappropriated germ power:† so that, until the maturity of growth, and in a ratio inversely to the age, there will always be the unexpended portion of the germ power co-operating with the properties of blood and vascular tissue in reparative actions; whereas, when the full maturity of growth has been attained, the reparation of an injury falls wholly within what, by analogy of language, we may call the *blood-power*:—that is to say, in a very young animal, specific forms not having been completed, there is a greater capacity of reparation than in an older individual, where these have been concluded. In the former example, growth is mingled with repair; in the latter, we have repair only.

If the scar or cicatrix of an extensive and deep burn be examined, it will be found that perspiratory pores and hairs are either very deficient or entirely absent in it; from which it would appear that the particular substance of the hair-follicles, and of the glandulæ of the skin, is not reproduced by the process of repair which has healed the wound.‡ In other cases, too, it appears that muscular fibrillæ, brain substance, liver substance, and the parenchyma of other organs, are not reproducible by the ordinary process of repair—the metamorphosis of lymph. Moreover, inflammation in the brain, in a muscle, in the liver, or in the kidney, does not issue in hypertrophy or increased natural growth of the particular substance of either of these organs, but in forms identical with those which characterise the process of repair—viz., lymph, new vascular tissue, lymph structures, granulations, and pus—and the metamorphosed forms of these—fibrous, tendinous, and osseous forms.

* Dr. G. Burrows relates an instance in which *phlebolites*, three in number, were examined by him and Mr. Stanley: two were of the size of almonds, and, upon being divided, exhibited several concentric layers of *fibrine*; in the other there was the same kind of structure, with osseous plates in the investing membrane. One of these bodies was attached to the lining membrane of the vein by *fibrous cords*; and a firm *fibrous band* connected this *phlebolite* with the others. Tiedemann, Otto, Lobstein, Cloquet, and Caruwell, all agree that at first *phlebolites* consist of a small coagulum of blood, in the interior of which the *fibrine* becomes pale and concrete; then assumes an *osseous appearance*; and this goes on, little by little, and layer after layer, towards the circumference. Dr. Reid, of Edinburgh, met with five instances of *phlebolites* within twelve months; they varied in number from two to a dozen; and in size, from a millet seed to that of a large pea. They were loosely attached to the coat of the vein, and nearly all of them were of a *stony hardness*. Two of these bodies were analysed, and found to consist of phosphate of lime, carbonate of lime, and animal matter, in proportions similar to those existing in *bone*. (*Pathological Observations on the Blood*: MEDICAL GAZETTE, Vol. xviii. 1834.—Edinburgh Medical and Surgical Journal, Vol. xliii. 1835).

† Vide Mr. Paget's Lectures on the Process of Repair: MEDICAL GAZETTE, 1849.

‡ Since this was written, the facts have been substantiated by Mr. Gray, who, in a paper published in the *Lancet*, speaking of the microscopical examination of the cicatrices of burns, states that "no hairs were observed covering the surface of these cicatrices, nor could the existence of sebaceous glands or perspiratory tubes be detected."

What are the inferences to be drawn from these facts? Simply, it appears to us, these: that phenomena of repair by the metamorphosis of lymph, and phenomena of inflammation, are both expressions, as it were, of exaggerated reciprocal action between blood and its containing-texture, and must be investigated apart from the properties of the particular substances prevailing in different organs; that the particular substances of different organs which are beyond the resources of repair, and which do not appear as results of inflammation, are not phases of blood-elements,—they are sustained and nourished by blood, but not derived from it:—whereas those elements and structures which do appear during the process of repair, or in the course of inflammation, are phases of blood-elements. These conclusions appear to derive additional confirmation from further embryological researches: for if the skin or integument of the early human embryo, before it has become vascular, be microscopically examined, cells of a peculiar character are seen grouped together, and disseminated through it in spots. These, from their symmetrical distribution, and the conformable spaces intervening, appear to be the foundations, or “*the germs*,” of what afterwards become follicles and glandulae. And as, in the most essential part of the embryo, the governing form (spinal cord and brain) is moulded before the circulation of blood, or the existence of vascular tissue,—so it appears in the skin that the particular substance of its hair-follicles and perspiratory glandulae is likewise established before the circulation of blood; and it might, *a priori*, have been concluded, that those substances, the germs of which exist prior to, or which are founded independently of blood and vascular tissue, would not be reparable or reproducible by the metamorphosis of the elements of blood, however necessary blood, in its aggregate capacity, may prove to be for their sustenance and growth.

[To be continued.]

MEDICAL APPOINTMENT—THE NORFOLK AND NORWICH HOSPITAL.

DR. RANKING has been elected Physician to the Norfolk and Norwich Hospital. The other candidates were Dr. Copeman and Dr. Wharton, the latter of whom retired early in the contest. The numbers polled were—Dr. Ranking, 364; Dr. Copeman, 236.

OR

SCARLATINAL VAGINITIS.

BY JOHN ROSE CORMACK, M.D., F.R.S.E.

Physician to Putney College; Fellow of the Royal College of Physicians of Edinburgh, and formerly Physician to the Edinburgh Royal Infirmary.

In 1844 I published in the *Edinburgh Monthly Journal* a memoir, entitled “Gonorrhoea and Syphilis with reference to Forensic Medicine and Therapeutics,” in which I directed attention to various topics, including non-venereal vaginitis. Since that period, several cases in my own practice, and others which have been mentioned to me by professional friends, have convinced me that exposure to cold, and other causes enumerated in the memoir referred to, are even more frequently the sources of inflammation and purulent discharges from the vagina than I supposed at the period of its publication.

At present, I only wish to say a very few words with reference to a paper which appeared in the *MEDICAL GAZETTE*, July 12, p. 65, by Dr. Robert Barnes, entitled “*On the occurrence of a muco-purulent discharge from the vagina in Scarlatina, and the importance of this symptom in relation to Forensic Medicine.*” Dr. Barnes attaches a much greater amount of importance to such cases than I was aware they possessed. He considers them very uncommon; and in support of this doctrine he cites two eminent authorities, Dr. Tweedie and Dr. Miller. I do not write in a controversial spirit, but simply with the view of inducing others for the future to inquire into the presence or absence of vaginitis in scarlatina. Dr. Barnes says—“I am quite prepared to accede to the opinion of Dr. Tweedie and Dr. Miller, that a muco-purulent discharge from the vagina in scarlatina is a very rare occurrence; but this very circumstance increases the importance of the symptom in relation to questions of legal medicine.”

During the last epidemic (1848-49) of scarlatina,* I had, under favourable circumstances, considerable, though not a very large, experience of the disease; and of all my cases I have preserved a

* Much information regarding this epidemic will be found in Dr. Miller's admirable monograph, lately published.

record. Vaginitis I frequently met with, and I regarded it in no way as an unexpected or rare occurrence; but, on the contrary, as a not unlooked-for extension of the *exanthematous* inflammation of the skin, analogous in its nature to what is often met with in the mucous linings of the nose, ear, air passages, and intestinal canal. In the epidemic of 1848-9 I had under my charge twenty-three female patients, all of whom were cleanly, well nursed, and in a respectable social position. In twelve of the whole number there was well-marked vaginitis; and so impressed was I with the importance of averting or preventing this affection, that in every female patient I directed, from the very first, careful ablutions of the parts to be performed at least twice in twenty-four hours. Of the twenty-three female patients, two only were above 14 years, and these were respectively 26 and 28, and both married. Now both of these patients had *acute* vaginitis, much more severe than any of the children. In one lady, for forty-eight hours the discharge was so abundant as to require the nurse to change the towels at least every hour, and it was of so acrid a nature as to excoriate the thighs and anus, notwithstanding every precaution being taken to protect these parts. The other had it more mildly; but the vaginitis was also in her a source of great suffering and discomfort. The first lady aborted: the second was not in the family way. The first was the most dreadful case of scarlatina which I have ever seen issue in perfect recovery: the second was one of moderate severity.

Speaking, as I now do, from a very limited number of facts, I have no right to give an absolute opinion as to the frequency or rarity of scarlatinal vaginitis; but I would venture to suggest that the non-observance of this affection by the practitioner is no proof of its absence; for patients suffering from scarlet fever are often too ill to make complaints: and in other cases the affection is managed by the nurse, without her thinking it necessary to trouble the doctor. The question must be decided by future experience of a large number of cases, carefully observed with a special view to its elucidation.

The whole treatment required is generally frequent ablution with tepid water, and, if pain be complained of,

the use of opiate fomentations. The children, with one exception, required very little special treatment; but one, of strumous habit, continued to have a profuse muco-purulent discharge long after convalescence was in all other respects complete. Chalybeate medicines, cod-liver oil, and astringent lotions, at last effected a cure. The two adults were both treated by injections of nitrate of silver, and the keeping apart the labia by a piece of lint soaked in the same. I believe in severe cases the nitrate of silver will be found the best local remedy: but the injury which it occasions to the linen of the patient, and of her bed, naturally occasions a prejudice against its use.

Essex House, Putney,
18th July, 1850.

HOMŒOPATHY IN NEW YORK.

AMONG the transactions of the New York State Homœopathic Convention, at their late meeting in Albany, was the adoption of a Constitution, which is to govern them, when in and out of convale. The preamble is as follows:—"We, the subscribers, physicians, residing in the State of New York, *believing* the law propounded by Hahnemann, '*similia similibus curentur*,' to be a fundamental truth in medicine, do agree to the following constitution" &c.—*Adapted without amendment.* We shall expect great doings in the Empire State among these innovators of medical science. Their flag is raised, and is given to the breeze; and the fact of their organization, it is supposed, will be wafted to the four parts of the globe. If any one can believe the mere doing of nothing to be a science, we have certainly nothing to say to such, farther than to advise the reading of Hahnemann on the peculiar and active properties of gold in certain diseases. He says, "after triturating one grain of gold with ninety-nine grains of sugar of milk, and continuing this trituration up to the *twelfth potency*, the remedial virtues of gold become roused to such an extent, that a man who was suffering with horrible melancholy, and who was impelled by intolerable anguish to take his life, needs but to *smell for a few moments* of such a preparation of gold, in order to recover his cheerfulness and love of life!"—*Boston Medical Journal*, July.

MEDICAL GAZETTE.

FRIDAY, AUGUST 2, 1850.

THE "Compensation in Railway Accidents" Bill, of the provisions of which we gave a short notice at p. 1117 of our last volume, was lost on the second reading by a very small majority of 2, in a house of 108 members. It was, of course, opposed by gentlemen connected with the railway interest for reasons which require no specification, and by the Attorney-General upon legal grounds.

We have already, at various times, fully considered the circumstances which led to the introduction of this bill. Our readers know, or ought to know, that, in the case of *Cox v. THE MIDLAND RAILWAY COMPANY*, it was decided by a majority of the judges that no action for the recovery of reasonable expenses or charges was maintainable by a medical man against a Railway Company whose servant had called him to attend a person who had sustained an injury. The bill proposed to alter the law, by giving a right of action against the Company to medical practitioners thus summoned to accidents by the Company's servants; and, to guard against injustice to a Company by the ignorance or officiousness of servants, the right of action was expressly limited to those cases only in which the accident arose from the negligence of the Company.

Mr. LABOUCHERE opposed the measure, because "it would provide that in all cases of accident the Company should be bound to call in medical aid, and be in the first instance responsible." This he described as a total departure from the law of the land. To this it may be replied, that every new Act of Parliament is a departure from the law of the land; the object of good legislation is to alter, amend, or suggest remedies for evils for which the current state of the

law does not provide: but the objection of the learned member may be tested by a case.

Through the negligence of a guard, a train is set in motion before the passengers have received fair warning. One is knocked down while stepping into a carriage, and he sustains a compound fracture of the thigh. There is no medical practitioner within five miles, and assistance is urgently required. Under the present state of the law the Company are not bound to call in medical aid, and, after the decision given in Mr. Cox's case, their servants will of course decline interfering for the benefit of the sufferer. If such an accident happened to any one of the 55 members who voted against the bill, it would no doubt be in his power to procure medical assistance at his own cost, and on his own responsibility, in the first instance. On his recovery he would claim compensation for his leg, or bring an action against the Company, and retain the best counsel,—say the learned Attorney-General, at a fifty-guinea fee,—to plead his case. On the assumption that there had been negligence, there would be a verdict with heavy damages, of which "the surgeon's bill would form an essential part."

But the victim of railway negligence may be a pauper; and, before considering the results in this case, we will quote the objections of the learned Attorney-General to the proposed bill. He said—

"he did not consider that the mere fact that conflicting judgments had been delivered could justify the house in adopting the principle of the bill. *He thought that medical men would willingly, on being sent for, render their services to a sufferer, even though they had no power of recovering payment from the Company, being assured he would pay them if he were able; and if he were unable to do so, having the certainty of remuneration, if he were an honest man, on his recovering damages, of which the surgeon's bill always formed an essential part.*"

It is pretty well known that the fees of barristers do not depend on any such series of contingencies as the learned gentleman would throw in the way of *medical remuneration* in railway accidents. The Attorney-General supposes that a hard-worked country practitioner would willingly leave his home and practice, and make a journey of five or ten miles, to take on himself the responsibility of attending a pauper seriously injured by a railway accident, with the full knowledge that the Company repudiated all liability, that the man was a beggar, and that the only chance of procuring payment for a heavy sacrifice of time and practice would be the "honesty" of the patient, and his recovering damages, by suing, *in forma pauperis*, a powerful Company, who would probably retain the learned Attorney-General himself, as well as other eminent barristers, for the express purpose of defeating his claim! The pauper might turn out an honest man, and might recover damages, in spite of the eloquence of the learned gentleman; but, on the other hand, the Attorney-General exerting his ingenuity for the Company might, notwithstanding the evidence adduced for the plaintiff, induce a jury to believe that the negligence was on the part of the man and not of the Company! In this case the remuneration for medical services rendered to the sufferer would be *nil*. Then, again, the pauper might die during the treatment. His widow might bring her action under Lord Campbell's act, and, under the same series of contingencies, she might or might not recover damages; and if recovered, she might or might not remunerate the medical man who had used his best endeavours to save the life of her husband. It is very true that the surgeon's bill always forms an essential part of the damages, but the party must obtain the damages before the bill could be paid; and the Attorney-

General might perchance be the advocate who would defeat the claim. The pauper may die, and not leave a survivor to make a claim: in this case, also, the remuneration would be *nil*!

As the law therefore stands, by the rejection of this bill, it is to be inferred that in railway accidents a medical man must be prepared to render his services gratuitously, at whatever cost or risk to his ordinary practice, in all cases except where *the party sustaining the accident is capable of paying the charges*.

If it be the case of a destitute person, the surgeon's chance of remuneration, in the event of his patient's recovery, depends—1. on clear legal proof of negligence on the part of a wealthy company sued by a pauper; 2. on the honesty of the plaintiff if he succeeds in the action; and, in the event of his death, 3. on his leaving a surviving relative who will succeed in an action against the Company, and be honest enough to discharge his bill.

The remuneration of gentlemen in the profession of the learned Attorney-General does not depend upon any such contingencies as these, and we are at a loss to know why they should be thus thrust on the members of another profession. As the law stands, medical men must often be called upon to accept them when accidents occur to the poor and friendless, or they must incur the odium of acting with unkindness and inhumanity to a fellow creature.

Mr. NEWDEGATE, in introducing the bill, related the following case, which had occurred on the Yorkshire and Lancashire Rne. "A dreadful accident had taken place, by which a man had his leg cut clean off, and the Railway people declined to send for medical aid, offering, however, to send him on to Bolton for admission into the infirmary; but when he arrived there he was dead, and so apprehensive were the railway parties of incurring liability, that the

poor man's leg was left by the road-side. Was such a state of things consistent with common humanity?"

It is possible that the measure which has been so recently introduced and rejected, may not apply the best remedy of which the case admits; but it is clear that, when under a railway accident to a poor person, a medical man must either abandon his other patients to give gratuitous attendance, or have imputations thrown on his character for humanity,—such a state of things requires to be immediately remedied.

Reviews.

On the Use and Abuse of Alcoholic Liquors, in Health and Disease. Prize Essay, by WILLIAM B CARPENTER, M.D., F.R.S., F.G.S., &c. &c., 8vo. pp. 283. London: Gilpin; and Churchill, 1850.

A PRIZE of one hundred guineas having been offered "for the best Essay on the use of Alcoholic Liquors in health and disease," the award was made to Dr. Carpenter's Essay.

The questions proposed were:

1st. What are the effects, corporeal and mental, of alcoholic liquors on the healthy human system?

2nd. Does physiology or experience teach us that alcoholic liquors should form part of the ordinary sustenance of Man, particularly under circumstances of exposure to severe labour or to extremes of temperature? Or, on the other hand, is there reason to believe that such use of them is not sanctioned by the principles of science, or the results of practical observation?

3rd. Are there any special modifications of the bodily or mental condition of Man, short of actual disease, in which the occasional or habitual use of alcoholic liquors may be necessary or beneficial?

4th. Is the employment of alcoholic liquors necessary in the practice of medicine? If so, in what diseases, or in what forms and stages of disease, is the use of them necessary or beneficial?

We shall endeavour to show our

readers the mode in which Dr. Carpenter has dealt with these questions, which embrace every point from which the subject of *teetotalism* can be viewed. It appears to us that Dr. Carpenter's answers are not so conclusive as he supposes.

We should not have thought it necessary to bestow much space upon this production, if the author, a well-known writer on physiology, had not assumed that a special obligation is laid upon the members of the medical profession to advocate a total-abstinence from the use of alcoholic liquors. We dissent altogether from this proposition. The duty of the medical adviser is to warn others against the abuse thereof,—and abuse, we may observe, does not consist alone in excessive indulgence, but also in the total disuse of this as of any other dietetic or prophylactic agent; and in using the latter term we claim for it a far wider meaning than the author assigns to it, in discussing the subject now before us.

Dr. Carpenter considers that the argument drawn from the abuse instead of the use of a thing, is completely defeated in reference to total abstinence by the late Archdeacon Jefferys, of Bombay. The theologian, seeing that the abuse of alcoholic liquors is the source of much crime and misery, makes use of the words of St. Paul; "It is good neither to eat flesh nor to drink wine, nor anything whereby thy brother stumbleth, or is offended, or is made weak;"—and thence proceeds to argue that this text is perfectly conclusive against even the most moderate use of alcoholic liquors. But that such is not in any degree true may be inferred from the same teacher's advice to Timothy in another passage: "*Drink no longer water, but use a little wine, for thy stomach's sake and thine oft infirmities,*" (1 Tim. v. 23). Here the moderate use of wine, it may be said, is positively enjoined. Moreover, upon this rendering of the text, the author should join the vegetarians, and henceforth forswear "flesh." Considering, therefore, that Dr. Carpenter has in no degree removed the objection—that the abuse of a thing good in itself, does not afford a valid argument against the right use of it—we proceed to the examination of his answers to the proposed questions.

1. The first answer consists of an

examination of the physical and chemical effects of *alcohol* on the animal tissues and fluids. With these our readers have no doubt become familiarized, in their attempts to preserve pathological specimens; but its action on the mucous membrane of the stomach of *living* animals yet remains to be accurately observed. With the effects of *alcohol* on the living structures without the body, our readers are equally familiar in the experiments of pathologists on the nature of inflammation.

The phenomena of alcoholic *intoxication* have been so often described in books, that we scarcely required Dr. Carpenter's fourteen pages of quotations to repeat the oft-told tale. In Dr. Carpenter's enumeration of the remote consequences of the *excessive use* of alcoholic liquors, we find the usual catalogue of diseases known to all clinical students. Dr. Carpenter borrows largely from the reports of officers in the Indian service, on the fatal effects of intemperance in tropical climates.

So far, then, as answer No. 1 is concerned, we discover nothing that was not known before, with regard to the *abuse* of alcoholic liquors, and it is on their *abuse* only that the author argues in this chapter. It will be observed that the word *alcohol* is almost universally employed by Dr. Carpenter. Now we need scarcely remark, that pure and undiluted alcohol never enters the system as a beverage. Even the most inveterate drunkards do not get beyond proof spirit. These, too, are exceptional cases, and cannot therefore be reasoned upon in the general argument. Dr. Carpenter, we may add, states no experimental researches in support of the chemical views he borrows from Percy, Liebig, and others.

2. The second answer founds its negative conclusion on the "indubitable fact in organic chemistry, that there is not the slightest relation of composition between *alcohol* and muscular tissue; and all our present knowledge of the subject tends to prove, that the albuminous matters of the blood, which constitute the pabulum of that tissue, cannot be generated within the body of man, or of any other animal, but are derived immediately from the food." Therefore, argues Dr. Carpenter, nothing can afford strength, or aid the nutrition of the body, except it contain albumen. But we think there are

other forces, besides the chemical, which perform an important part in the nutrition of animal frames. We have heard of a certain condition of organization, called *vitality*, which has usually been supposed to exert some influence over chemical actions going on in the living body. Moreover, we do not forget that the human frame does not consist solely of, and depend solely upon, the muscular system for its existence—there is a system closely connected therewith, and this is the nervous system. Dr. Carpenter has not disproved the beneficial effects of moderate doses of alcoholic liquors on this system.

Dr. Carpenter observes in reference to the use of alcohol in sustaining the vital powers:—"It may be safely affirmed that the introduction of alcohol into the blood cannot stand in the place of the oxygen which is essential to the functional activity of the nervous and muscular systems." Undoubtedly this may be very *safely* affirmed, for no one can dispute the statement. It appears to have as little bearing on the argument, as the assertion that the vapour of chloroform cannot supersede atmospheric air in the lungs.

It may suit Dr. Carpenter's purpose to throw overboard the "universal experience of former generations," by remarking, that it "might be quoted in favour of a multitude of absurd notions which we now treat simply as ridiculous." But this remark does not, in the present case, dispose of *universal experience*, the inference from which, we assert, remains still untouched by the instances of bodily effort put forth by "temperance" men, quoted by the author from various writers.

Dr. Carpenter argues, from the facts of organic chemistry, that *alcohol* cannot either enable the human body to endure cold or contribute towards the maintenance of its heat; but "universal experience" refutes the speculation; and we may observe, that experiments which Liebig performed directly with reference to these points led him to the very opposite conclusions. In a previous portion of his essay Dr. Carpenter relied much on Liebig's researches; but here his observations are laid aside. This *ch* further enumeration of facts of the *exce* liquors on variou

8. In his third answer, however, Dr. Carpenter admits that there are cases,—such as those “in which there is a demand for some extraordinary exertion of the animal powers, and in which the occurrence of subsequent depression may not be an adequate objection to the employment of a stimulus that enables the system to meet it”—in which the effect of the stimulus is merely to keep the functions “up to par.” In the same chapter the author admits that the moderate use of alcoholic liquors is very beneficial in contributing to the endurance of bodily labour under circumstances peculiarly trying, and under the disadvantage of a deficient allowance of animal food. Where there is a deficiency of constitutional vigour, also, “the author is by no means disposed to deny, that after all other practicable means have been taken for the invigoration of the system, the habitual use of a small or moderate quantity of alcoholic liquors may be found beneficial in some individuals.” The author again, at the conclusion of this chapter, argues against the use of alcoholic liquors from their abuse. Because in pregnancy, lactation, old age, &c. their use has been abused, no sound argument, we reiterate, can be drawn for their total disuse. In the existing state of society, the exceptions here admitted must embrace sufficient numbers to invalidate the rule.

The fourth answer enters into the consideration of the use of alcoholic liquors as medicinal agents. With these the majority of our readers are experimentally acquainted; and, as we discover no new information in Dr. Carpenter's remarks, we may here close our examination of the author's answers to four plain questions.

We confess that we regard these answers, at best, as unsatisfactory if not evasive. They deal throughout with the *abuse* of alcoholic liquors, the evils of which have long been too well known. In many instances throughout the work, the word *alcohol* is used for *alcoholic liquors*, whereby the non-professional reader is misled as to the results. Lastly, the author himself admits sufficient exceptions to invalidate the arguments in support of *total abstinence*.

We expected, from the author's reputation, to have met with a new series of experiments in support of his views;

but we find nothing more than the old arguments drawn from old facts—whence the sole legitimate deductions are, that temperance is wisdom, teetotalism a delusion, and the abuse of a thing good in itself is no valid argument against its proper use. Therefore, under the conviction of the accuracy of these conclusions, we arrive at the inference, that it is not the duty of medical men to advocate total abstinence.

In conclusion, we cannot think that *teetotalism* has very strong claims upon the attention of any class of society, if the treatise before us be the best among those which were presented in competition for this hundred-guinea prize. It is clear, from Dr. Carpenter's essay, that teetotalism has not much to be said in its favour, when its professed advocates virtually abandon its pretensions, by failing signally, on a special occasion, to adduce either facts or arguments in its favour.

We may commend this essay, nevertheless, as containing much useful information, and many powerful warnings to those who have not the strength of mind to be “temperate in all things.”

—
On the Diseases of Menstruation, and Ovarian Inflammation, in connection with Sterility, Pelvic Tumors, and Affections of the Womb. By EDWARD JOHN TILT, M.D., &c. 8vo. pp. 250. London: Churchill. 1850.

THE principal diseases (derangements?) of menstruation, as enumerated by Dr. Tilt, are—amenorrhœa, or suppressed menstruation; dysmenorrhœa, or painful menstruation; menorrhagia, or profuse menstruation; leucorrhœa, or vicarious discharges; and hysteria. These names, Dr. Tilt is of opinion, have been very vaguely used, since, among their causes, various contradictory conditions may be mentioned, and are pointed out by the author, whose object, however, is not to treat of the several organic diseases by which they are frequently produced. The work before us is confined to the consideration of inflammation of the ovaries and oviducts. From this limitation it is evident that the author has adopted the ovular theory of menstruation proposed by Dr. Robert Lee and Dr. Power. This is made still clearer by the author's definition of menstruation, which is—“A sero-sanguinolent secretion propelled by an ova-

rian influence from all or different parts of the generative intestine, and principally from the womb." The author has not, however, lost sight of various facts which are strongly opposed to the theory.

Dr. Tilt enumerates the British and foreign writers who have furnished materials for a history of ovaritis; "but it has been of acute ovaritis," the author remarks, "that these have treated, while the sub-acute variety, judging by the inflammatory lesions found in the ovaries and their serous covering, is of very common occurrence." (p. 15.) It is more especially to give due prominence to this form of ovaritis, with its consequences, that the author has published his views, for which so far he claims originality. But we will here quote his words:—

"My aim has been to perform for the ovaries, the principal organs of menstruation, what has been successfully done for other organs by many eminent men; and I feel assured that, although some of my deductions may be contested, my practice will be admitted by all to be indubitably safe, and necessarily destined to diminish the number and intensity of female complaints.

"I can lay claim, *unfortunately*, to no discoveries; but from an acquaintance with the literature of that branch of the profession to which I have devoted my chief attention, I feel justified in affirming, that in no other work will the reader find so complete an account of the various ways in which sterility is produced by the action of inflammation in the ovarian tissues, of the great importance of ovarian peritonitis as a cause of disordered menstruation, or of the influence of ovarian inflammation in the production of uterine disease,—facts forcibly exemplified, and proved to be not mere conventional possibilities, but events of frequent occurrence."

Such, then, are the principal points under consideration by Dr. Tilt; and we now proceed to show the author's manner of expounding his information on these topics.

Subacute ovaritis is defined by Dr. Tilt thus:—"Swelling of the ovary, with increase of heat and pain upon pressure, accompanied by intermittent or permanent pain or uneasiness in the ovarian region, radiating to the loins and thighs, and producing, according to the constitution of the patient, an arrest of menstruation or its profuse flow, intense local pain or hysterical symptoms." (p. 89.)

"By *subacute* inflammation, as distinguished from *acute*, we do not so much imply a difference in the intrinsic nature of the morbid phenomena, as a limitation of the inflammatory action to certain distinct parts of the ovaries, as the ovarian follicle, and to portions of the ovarian tissue so small that they will give rise to no swelling and to little febrile action."

Among the predisposing causes of ovaritis, Dr. Tilt places the anatomical relations of the organs, constitution, excessive sexual intercourse, and the impulse of unsatisfied desire. Among its exciting causes are enumerated falls on the feet, knees, or sacrum, violent horse exercise immediately after menstruation, instrumental labour, adhesion of the placenta, styptic and other injections into the cavity of the uterus, retention or suppression of the catamenia, cold, peculiar condition of the nervous system at the time of menstruation, extension of inflammation from uterus to ovaries by the Fallopian tubes, cauterization of the cervix uteri, and the employment of certain mechanical contrivances.

The symptoms, as described by Dr. Tilt, are those of a local and of a general character: these are often referred to uterine disease or to inflammation of the bowels. Dr. Tilt distinguishes also special symptoms, which he distributes under the several types—amenorrhœal, dysmenorrhœal, menorrhagic, and hysterical.

The terminations of sub-acute ovaritis, according to Dr. Tilt, are sterility and uterine inflammation. Sterility is in these cases produced by—1, the accelerating the shedding of imperfectly developed ova; 2, by the retention of blighted ova in the ovary; 3, by placing mechanical impediments to their transmission from the ovaries to the uterus. The transmission of the ovarian inflammation produces congestion and hardness of the womb, with consequent retroversion, and perhaps peritoneal inflammation. Cases of this kind are related in illustration by Dr. Tilt. One case, at page 116, is deserving of notice, as containing a candid record of erroneous diagnosis on the part of the author. Practical medicine would make substantial progress if its professors would more frequently record their errors; and certainly in no department would the benefit be so great as in that of uterine pathology, in which we hear

now-a-days of a thousand successful cases without a single reverse!

On the subject of *treatment*, Dr. Tilt remarks that it must be observed as a fundamental point of practice that the treatment must be conducted in the intervals of the menstrual periods. With regard to depletion, which the author enjoins to be of a local character, he remarks:—

“Whether, in these cases, any particular advantage follows the application of leeches to the os uteri, or its scarification, we very much doubt, on account of the uncertainty of the results; we think that, even if it did afford sometimes any slight relief by the immediate depletion of the uterine vessels, such an advantage would be purchased at the risk of uselessly offending the patient's feelings by the untimely interference of a surgeon, by whom the application of leeches must generally be made.”

The author also states other objections to this mode of depletion, as also to that of leeching the rectum, as practised by Dr. Rigby. We feel thankful to every writer who lends his help to stay the current of professional indifference, or worse, which at present treats female delicacy with utter disregard.

We commend the author's remarks on the treatment of subacute ovaritis as judicious, and (with the exception of the recommendation of the medicated pessary) as being free from the prevalent vice of too active manipulation on the female sexual organs.

Acute ovaritis forms the subject of the concluding portion of Dr. Tilt's treatise, and presents a full account of that form of the disease in its different varieties. The several modes of evacuating the pus of acute ovarian tumors are also related. *Acute ovaritis* is, however, not so much the object of Dr. Tilt's work as *subacute*;—to point out the relation of this to derangements of menstruation has been his direct aim. In so doing the author has assumed, as we have before observed, the ovular theory of menstruation as his basis. Whether this be universally received as correct, or hereafter rejected as pure hypothesis, in accordance with some facts mentioned by Dr. Tilt, as well as other considerations, the practical result will remain, that a close functional relationship exists between the uterus and ovaries. That a close relationship also exists in disease has, we think, been here shown by Dr.

Tilt; and while we fully appreciate the value of the information contained in his work, we would remark that, in our opinion, he has scarcely meted out a fair share of praise to the previous researches of British pathologists.

Instinct and Reason: deduced from Electro-biology. By ALFRED SMEE, F.R.S. 8vo., pp. 320. London: Benham. 1850.

THE inconclusiveness of Mr. Smees' electro-biological theory was shown in our notice of his “Elements of Electro-biology,” at p. 590 of our last volume; it is therefore unnecessary now to occupy our space with any remarks upon that part of the present work. We shall simply enumerate the contents of the present volume, premising that the author explains all the instances of instinct and reason which he adduces, by assuming as their causes the occurrence of certain voltaic changes in the nervous system.

The first chapter contains general observations on the “relation of mind to life,” or on the common phenomena by which organized beings are distinguished from inorganic substances. In this chapter we find mention of the *œmæ* of Messrs. Croese and Weekes, on which Mr. Smees observes—“I am of opinion that the facts should be neither believed nor disbelieved, but kept in abeyance for fresh experiments.” For ourselves, we thought that this “act of creation” had been disposed of some years ago in an article published in the *Edinburgh Review*, and which has been attributed to Professor Sedgwick.

In the next chapter we have a description of the organs of sense, with their degree of perfection in different animals, and Mr. Smees's invention of the Optometer. The author observes that he “never remembers to have seen, amongst the thousands of books now published, any work upon the science of odours.” We may refer Mr. Smees, for a short notice of this “science,” to a book of travels, very genuine and authentic doubtless, lately published, and entitled “*Kaloolah*,” in which the author, an American surgeon, having arrived at one of the kingdoms of Central Africa, finds people's noses cultivated with all the care for the appreciation of odours, with which the ear is cultivated among ourselves for the en-

joyment of musical sounds. Mr. Smee might insert this *fact* in his next edition.

Among the author's illustrations of the physiology of the organs of sensation we find the following:—

"The estimate of heat and cold is highly important, and man possesses this feeling to a great extent. Whilst I am writing, a blazing fire is casting its radiant heat upon my body, and comforts it; but, were I to cross my threshold, a cold, biting north-east wind would chill my skin and make me sensible of the change of temperature."

Again:—

"The skin is endowed with nerves for the purpose of estimating heat and cold. In this respect the human species is not singular; for, as far as I can observe, all other creatures are sensible to heat and cold: and, whilst I write, my cat is lying before the fire, and the dog is standing with his feet on the fender, the better to warm his chest." (p. 36.)

The third chapter expounds the existence of pain, and its uses.

Memory forms the subject of the fourth chapter, in which instances of its manifestation in the lower animals are related. We may quote the following instance of its exercise in man:—

"I was once at an important meeting where no reporter was present, and it was desirable for a report to appear. Upon application two or three days afterwards, I wrote out such of the speeches as were required, in such a manner that the substance was so correctly given that no person found out that his very words had not been taken down in the room by a shorthand writer. Those proceedings happened to interest the public, and have been copied from paper to paper, and from newspapers to standard works. When I have seen the extracts I have often smiled at the utility of memory which could thus accurately have given the result." (p. 52.)

The fifth chapter, on Reason, contains some examples of memory in animals, and of the degree to which they are capable of education or training.

The superiority of the operations of man to those of animals constitutes the subject of the sixth chapter. This is shown at considerable length by an account of the author's process of electro-metallurgy, voltaic chemistry, and other applications connected with electricity; also by railways, photography, &c. &c. Extracts are also given from the reports in the daily papers of an exhibition of

various kinds of bread by Mr. Smee, at a *soirée* at his house, in February 1847.

The great distinction that Mr. Smee draws between man and animals, in reference to the subject of the chapter, is, that the former makes and varies his own tools, the latter uses only those with which he is furnished ready-made by nature.

The chapter on Instinct contains accounts of the construction of the nests of insects and birds. This is followed by a chapter on intuitions, or "intuitive instinctive ideas." The ninth chapter, "On Words and Language," includes the consideration of how far these have been imitated by animals, and treats of the means of communication among animals, as well as the extent to which they comprehend words addressed to them by man.

The tenth chapter treats of the limitation of the operations of man as compared with those of nature.

The next chapter contains the author's theory of Instinct and Reason, comprising, first, the theory of electro-biology: these are followed by "Principles of the Human Mind," expounded in sixty-eight aphorisms, or propositions, expressed in the language of electro-biology, and quoted from the author's "Elements of Electro-biology." The nature of this theory of instinct and reason may in some measure be judged of by the following extract:—

"Upon this theory man only differs from the dog inasmuch as he has a higher organisation—a more elaborate structure; but, whilst man lives on this earth, there is no reason to suppose that any other faculty than this elaborate structure comes into operation."

A very material theory! The twelfth chapter, however, "On Reason and Faith," reconciles electro-biological theories of reason with revelation:—

"I have much cause (the author states) to rejoice that the system of electro-biology which I have developed, after many tedious hours of investigation with the midnight oil, and after many years of anxious thought, should now be found to be a system deduced by reason, and in perfect accordance with that religion which I hold by faith."

In the next chapter, on "Perverted Reason," the author notices errors of sense, delusions, mania, and the potato disease, with its relation to the *aphis vastator*.

We extract the following paragraph in reference to homeopathic globules:—

"Perhaps nothing is more remarkable than the nature of these globules. Each weighs about the 1-25th of a grain; and they are sold in little bottles labelled 'arsenic,' 'camphor,' 'musk,' &c. Now it has been stated that a grain of musk will scent a room for twenty years; yet some labelled musk which I examined had no odour. With regard to arsenic and copper, the refinements of modern chemistry can detect extremely minute quantities; yet the most eminent chemists have failed to obtain indications of the slightest trace of these materials: and be it remembered that the globules which have been examined have been taken from chests which, according to the statements of their owner, have produced wonderful cures. It is the common belief that all the globules are made alike; but it cannot be denied that occasionally those who practise homeopathy contrive to substitute active doses of the more deadly poisons when they are persuading their followers that they are but giving them harmless globules" (p. 273).

We believe that the author is quite correct in stating that the globules are all made alike. They probably contain nothing but sugar of milk. It is a curious fact that, whether they are labelled arsenic or mercury, camphor or cayenne pepper, each globule weighs the same, i. e., the 1-25th part of a grain, and all are of the same size, as if formed in the same mould. Hence it follows that there is either no medicinal substance in the globules, or there must be a wonderful accommodation in the doses—i. e., the lighter the medicine the less the quantity required, or it would affect the bulk!

The work concludes with a notice of the classifications of the various families of man and animals, and the proposition of a new natural classification on electro-biological principles. The proposed classes are to enjoy a very classical nomenclature; such as *Aisthemic*, *Syndramic*, *Noemic*, *Pneuma-noemic*, and *Dynamic*. The classification and its subdivision appear, however, to us, quite as artificial as any other ever proposed.

The work is furnished with well-executed coloured and plain engravings of some of the various objects brought under notice in its pages. We have discovered but little that is new in the volume: for this, however, we should not have looked, as we perceive that

the author informs us in his preface that it has been compiled as an amusement rather than a labour—a relaxation from the fatigues and anxieties of previous occupations. The author also states that he has preferred selecting his illustrations from facts of his own observing, "in preference to those which, although more remarkable, have been observed by others." It has appeared to us, that if Mr. Smee's observations and reasonings had been diligently compared with those of other investigators, his theories would have been more intelligible,—he would have been enabled to place a more correct estimate on his own labours, and science would have derived greater benefit from the contributions of so zealous and indefatigable a cultivator of the phenomena of nature. Apart from the author's peculiar theories, the book contains much that is interesting and suggestive in reference to the instinct of animals.

On the Structure of the Membrana Tympani of the Human Ear. By JOSEPH FOYNSSE, F.R.S., Fellow of the Royal College of Surgeons in England, and Senior Surgeon to the St. George's and St. James' Dispensary, London.

In this paper the membrana tympani is described as consisting of the following layers, which are quite distinct from each other, both as regards their structure and functions:

1. Epidermis.
2. The proper fibrous layer, composed of
 - a. the lamina of radiating fibres
 - b. the lamina of circular fibres.
3. Mucous membrane.

One of the principal objects of the paper is to describe the structure and functions of the fibrous laminae. Since the time of Sir Everard Home, who pronounced the layer of radiating fibres to be muscular, anatomists have differed in their views of the nature of the fibrous element of the membrana tympani. The lamina of radiating fibres, the outer surface of which is covered by the epidermis, is described as continuous with the pericottum of the external meatus. With the exception of the uppermost fibres, which, on account of their

being somewhat floccid, have been considered as a separate tissue under the name of "membrana floccida," the radiated layer is composed of fibres which extend from the circular cartilaginous ring to the mallens, and there interlace in their course. These fibres are from 4000 to 6000 parts of an inch in breadth.

The lamina of circular fibres consists of circular fibres which are firm and strong towards the circumference, but very attenuated towards the centre. The fibres are so attached and arranged as to form a layer of membrane, which, in a quiescent state, is saucer-shaped.

The fibres composing the circular are smaller than those of the radiated lamina, being from 6000 to 10,000 parts of an inch in breadth.

The facts that appear to be adverse to the idea of the fibres of either layer being muscular, are:—

1st. The absence of distinct nuclei in the fibres.

2nd. Their great denseness and hardness.

It is next shewn that the four laminae forming the membrana tympani are continuous with other structures of which they appear to be mere modifications, and that not one is proper to the organ.

The tensor tympani ligament, which had not been previously noticed by anatomists, is particularly described; it is attached externally to the mallens, close to the insertion of the tensor tympani muscle, and internally to the cochleariform process.

The latter part of the paper is occupied by observations on the functions of the fibrous laminae and of the tensor ligament of the membrana tympani, and it is shewn that, by these two antagonistic forces, the one tending to draw the membrana tympani outwards, the other inwards, this organ is maintained in a state of moderate tension, and is always in a condition to receive ordinary sonorous undulations.

Cholera in Packet-ships.

M. GYRARDIN read a report from M. Renault relative to the appearance of the cholera on board the packet-ship *Luxor*, in October and November 1849. The *Luxor* having remained thirty-five days at Marseilles, where the cholera prevailed, left that port with crew and passengers in good health. During the first few days several men had choleraic symptoms. On the seventh day one of the sailors was seized

with malignant cholera. From this time an epidemic focus—(focus of contagion?)—was formed, under the unfavourable influence of damp, want of ventilation, fatigue, crowding, &c., and cases of cholera and diarrhoea multiplied. On the eleventh day another sailor was attacked with cholera. On the arrival of the vessel at Smyrna the passengers, crew, and cargo, were landed; and every hygienic precaution being adopted, no fresh case occurred.

M. PELLERIN related a large number of facts proving the transmission of cholera by contagion, which he had observed in the districts of Finisterre and Côtes-du-Nord during the late epidemic.

SURGICAL SOCIETY OF PARIS.

July 17, 1850.

Cutaneous Affection of a doubtful character.

M. HUGUIER presented the following case to the notice of the Society:—A young negress having had an irritating application on the chest for some internal affection, there appeared on the surface several small, hard, painless tumors, about the size of a small nut. The skin on these tumors did not differ from the rest of the integuments. A slight depression existed on their summits.

M. Huguiet had removed several of these growths, and a smooth cicatrix was left. In external character they resemble the cancerous disease termed *Keloids* by Alibert. M. Huguiet regarded them as consisting of an hypertrophy of the follicles of the hair,—a form of disease which he had before described under the name of *acanthriopsia*.

MM. LABREY and GOSSELIN concurred in the opinion.

M. GERALDES thought it analogous to the form of disease known in England as chimney-sweeper's cancer.

M. CHASSAIGNAC exhibited an exostosis removed from the tibia.

M. MALBONNEUX also presented a specimen of disease of the elbow removed by operation.

Degeneration of the Structure of the Heart.

M. VERNEUIL exhibited a specimen of ossification of the pericardium covering the heart, and of rupture of the right auricle, found in a female body which had been appropriated for dissection. The wall of the auricle had undergone a cretaceous degeneration over a considerable extent. The heart was hypertrophied, and its substance flabby. Blood was found extravasated under the pericardium of the auricle.

Case of Utero-placental Hemorrhage.

M. BIOT exhibited an ovum which had been expelled at two months, about the size of a hen's egg, of a livid red colour, and presenting all the appearance of a clot of blood. It was found to consist of an extravasation of blood filling the interspace of the decidua and chorion. The coagulum was thicker and denser at that portion of the chorion from which the placenta was developed, the vessels of which appeared to have been the source of the hemorrhage. No communication had existed with the cavity of the amnion. An aperture was detected in the latter membrane; whence it was ascertained the fetus had been expelled entire three days previously. The umbilical cord was found floating in the cavity: no trace of umbilical vesicle could be discovered.

M. BROWN-SQUARD also exhibited several fetal rabbits, with which hemorrhage had taken place into the cavity of the amnion. The mother had died of acute pleurisy.

On the Constant Presence of Cystoeceri in Rabbits.

M. BROWN-SQUARD stated that he had examined upwards of eighty rabbits, and always found cystoeceri in the abdominal cavity: he therefore considered their occurrence to be constant. An example of their presence in the rabbit's abdomen was exhibited.

Inoculation of Secondary Syphilis.

M. VIDAL (of Cassis) communicated to the Society the results of his experiments, showing—that the matter of the ecthymatous pustule may be transmitted by inoculation from one patient to another, and from the diseased to the healthy individual.

Fibrous Polypus of the Rectum.

M. HUGUENI related the particulars of a fibrous polypus, which he had removed from the rectum by means of a double ligature. The fibrous character of this polypus was doubted by some members, who regarded it as a fleshy substance, resulting from hypertrophy of the mucous membrane of the rectum.

BIOLOGICAL SOCIETY OF PARIS.

PRESIDENT, M. RAYER.

Monthly Summary, April 1860.

Explanation of Crossed Paralysis of Sensation. By M. BROWN-SQUARD.

THE author stated, that, from his investi-

gations and experiments, he had arrived at the conclusion that the interlacement of the sensitive fibres of the spinal cord throughout its whole length completely explains the phenomenon of crossed paralysis of sensation; and that the various points of interlacement usually referred to the medulla oblongata, pons varolii, &c. are insufficient to explain the phenomena.

Mucous Membrane expelled from the Uterus during Menstruation.

M. LEBERT described a membranous sac, of the shape and size of the cavity of the uterus, expelled during a paroxysm of painful menstruation. This substance measured four centimetres (=1.74 Eng. inch) in length, and from two and a half to one centimetre (=.983 — .893 English inch) in breadth, and about one centimetre (=.893 Eng. inch) in thickness. It presented three apertures corresponding with the os uteri and orifices of the tubes. Internally, its surface was lined with pavement epithelium, the cells of which were from an eightieth to a ninetieth of a millimetre in diameter, enclosing an ovoid nucleus, and these again containing nucleoli.

M. Lebert considered that this pathological specimen lent confirmation to the opinion of those physiologists who consider that menstruation is normally attended with the formation and expulsion of a false membrane, analogous to the decidua of pregnancy.

ACADEMY OF SCIENCES, PARIS.

July 22nd, 1860.

New mode of removing Wens—their Composition.

M. A. LEGRAND having several times witnessed fatal consequences following the removal of wens by incision, had been induced to practise the following operative proceeding:—The skin around the base of the tumor was divided by repeated linear applications of pure potash; by the continued employment of these, the line of eschar becomes deeper, until the tumor is detached. It is necessary in this way, as with the knife, to destroy the whole growth, or it will re-appear. M. Legrand had put this plan into execution thirty-two times, without erysipelas or any other ill result having followed.

M. Legrand added, that having examined two wens, one from the scalp, the other from the forehead, he had found that the one consisted of an hypertrophied sebaceous follicle, and that the pathological basis of

the other was a hair follicle. The contents of both were chiefly fatty matter, epithelium cells, and granules. In that removed from the forehead, crystals of cholesteroline were found in abundance.

Employment of Adonis vernalis in Ague.

MR. SIMON ST.-PIERRE stated the results of seven trials with this remedy. Three doses of thirty grammes (nearly an oz. Eng.), boiled in about a pint of water, had proved sufficient to arrest the disease in each instance.

Hospital and Infirmary Reports.

KING'S COLLEGE HOSPITAL.

Operations.

SEVERAL operations of interest have been recently performed by the surgeons of this hospital, and we shall give a short description of each of them.

The first case was one which is of particular interest, inasmuch as it presented an instance of the power the surgeon possesses of removing by manual proceeding the deformity which results too often after the cicatrization of a wound caused by a burn. The patient, who was a little girl about ten years of age, had been burned some time ago in the left arm. The injury affected the parts just in the flexure of the elbow-joint. It is probable that so much precaution as was necessary in these cases was not taken; for as cicatrization had ensued, the elbow became contracted by the firm puckering of the integuments. In order to set this free, Mr. Fergusson performed the following operation:—By two nearly parallel incisions he included the old cicatrix, which was about three inches in length, and dissected it cleanly away from the tissues beneath. Another incision, at right angles to the former, about an inch in length, was then made, for the purpose of taking off the tension of the parts, and the edges of the wound were brought lightly together with thin sutures. This operation, although simple in appearance, requires great neatness and care in its execution; and much precaution is necessary in the after-treatment of such cases, as there is always a very great disposition in the parts to contract after they have been liberated. Mr. Fergusson stated that the plan he had just adopted was very similar to the one recommended by Sir James Earle, and that it was the most likely to be successful in the removal of such contractions.

The next operation was one of a somewhat peculiar nature. A young child was brought into the theatre who had the vulva entirely closed, no orifice being seen but that of the rectum, which was marked, in fact, more by a protrusion of the mucous membrane of the gut than by any very discernible outlet. From the upper portion of this the urine came away when the child made efforts to pass water. Above, in the situation of the vagina, was a long cicatrix, on a completely smooth surface, the effects of sloughing which had some time ago ensued after an attack of measles, and had ended in complete obliteration of the female external organs. It was for the object of restoring the passage that Mr. Fergusson operated to-day. He first distinctly made out the situation of the rectum, and that of the opening of the urethra; and then, with a bistoury, carefully laid open the whole length of the cicatrix. This was readily effected, so that the finger could be passed with ease up the vagina. The septum between it and the rectum was found to be entire, and the hymen untouched. The parts were kept patent by pledgets of lint introduced between the lips of the newly-made wound.

The next operation was performed by Mr. Bowman upon a young man who had a very curious tumor situated upon the forehead; chiefly, indeed, implicating the substance of the upper eye-lid, and extending from thence for more than two inches up along the integuments of the frontal bone. It appears that this tumor had been growing there ever since the patient was two years of age, at which time he had received a blow on the spot where the abnormal growth was situated. It was so prominent that it partly closed the eye, and it gave to the touch the feeling somewhat similar to that which is experienced on handling a bunch of enlarged veins of the spermatic cord. The tumor could also be partly pushed upwards from the orbit to the frontal region. There was no discolouration, and no pulsation particularly could be felt. Both Mr. Bowman and Mr. Fergusson considered it to be a vascular tumor; and it was deemed advisable to obliterate it by means of an operation, partly performed by the knife, partly by the needle and ligatures. It was not deemed safe to extirpate it entirely by the knife, as it was considered to be of so vascular a nature that serious hemorrhage might result. The ligature alone could not well be used, as this would cause a considerable loss of skin, which would produce a greater deformity than the tumor itself. A modification, then, of both these plans of treatment was very skillfully and judi-

ciously used by Mr. Bowman. He first incised the integuments freely over the mass, and laid them on one side, so as to expose the greater portion of the swelling situated in the orbit. He then, with needles and strong thread, surrounded the base of the tumor, and firmly strangled it. Whilst making the incision with the knife, smart bleeding took place from many arterial vessels which were divided. This, however, was easily checked by the assistant compressing each of them with his finger as they were divided. Mr. Bowman then laid bare the upper portion of the tumor, and used the ligature: he also removed a portion of the tumor. After the mass was firmly strangled all bleeding ceased, the skin was brought lightly over the wound, and the patient was carried to bed. Mr. Bowman stated, as regards the precise structure of the tumor, that it was impossible, without a minute examination, to speak with certainty about it. Both Mr. Fergusson and himself had considered it to be a vascular tumor, composed chiefly of veins; but it was evident that it consisted chiefly of arterial ramifications.

Mr. Partridge had an interesting case in which he operated. A patient of his had lost about an inch of the integument of the penis, and the urethra had been laid bare and perforated. The consequence was that all his urine came away by this artificial opening, and of course this condition was a source of great discomfort to the patient. Mr. Partridge determined to endeavour to close the opening, and he performed the operation in this manner:—He first carefully dissected back the skin, by making an incision on each side and at each extremity of the wound, thus forming a somewhat quadrangular flap. The edges of this flap were then pared: this constituted the first part of the operation. The main point, however, in the process is to bring the parts accurately together, and to keep them in this position until the wound may have healed. There are various methods of doing this. Mr. Partridge made use of the *dead suture*, which is well adapted for operations of this kind. He used it according to the manner, and by means of the very ingenious instruments invented by Mr. Charles Brook. By means of these sutures the wound was accurately closed, and the operation was concluded. The catheter which was placed in the urethra prior to the operation was allowed to remain there.

Tumor of the Upper Jaw.

On Saturday, June 22, Mr. Fergusson operated on a patient who had disease of the upper jaw, and whose case presented

features of great interest. A few weeks ago we reported a case where there was disease of the upper jaw, which was considered to be of a malignant character, and requiring excision of the whole of the affected bone. Mr. Fergusson, however, doubted the nature of the disease; and, prior to performing the operation which had been considered necessary, he deemed it prudent to puncture the swelling. On this being done, it was discovered to be a collection of viscid fluid in a much dilated antrum. A portion of the wall of the antrum was removed, and the cavity was kept open. A free discharge of the fluid was thus allowed. The parts contracted much, and the patient went out well, or nearly so. We here refer to this case because there is a great resemblance between it and the one now under notice. In the former the patient was a young woman, and the disease had not been noticed for more than a twelvemonth. In the latter case the subject is a man between 40 and 50. He first noticed the disease seven years ago, but did not have any surgical attendance until four years ago, when, as the swelling of the jaw had increased, he applied to a surgeon, who punctured it, and let out a quantity of reddish-looking fluid. This continued discharging some time, when the wound closed up; but some time ago it broke of its own accord, and has continued discharging ever since. On his application to the hospital there was a considerable prominence of the superior maxilla on the right side, but there was no protrusion of the palate. An orifice existed in the upper alveolar border, from which a yellowish discharge took place. This came evidently, as could be ascertained by a probe, from the antrum. By pressing firmly on the lower wall of the antrum, it could be felt to be slightly moveable; and a creaking noise was heard, indicating the entrance and exit of air: at the same time, this movement increased the flow of the fluid from the cavity in which it was contained. It was very evident what was the nature of the disease. Mr. Fergusson pronounced it to be not a solid tumor of the jaw, but a dilated antrum secreting constantly a peculiar fluid; and, as the enlargement disfigured the patient much, and he was very anxious about it, he determined to remove the disease by operating in the same manner as he had done in the former case. The patient was placed under the influence of chloroform, —a proceeding which is objected to by some surgeons in the operations on the upper jaw; but Mr. Fergusson always uses it in his operations on this locality. We have seen him remove the superior maxilla in several instances when the pa-

tients have been under the influence of chloroform, and there has appeared to be no more danger or distress connected with it than if the operative proceedings were being carried on on any other part of the body. There is some difficulty in keeping the patient long under its influence, as the surgeon's hands are in the way, and prevent the application of a handkerchief or mouth-piece; but Dr. Snow manages to keep up the anæsthetic influence by applying a sponge with some chloroform on it every now and then to the nostrils and mouth.

Mr. Fergusson first laid open the upper lip, carrying his incision a little to the right through the nostril. He then dissected it from off the palate, and fully by this means exposed the expansion of the upper jaw. He then, with a sharp pair of curved bone forceps, removed about a square inch of the anterior wall of the antrum, which was lined by its membrane, of considerable thickness. The divided lip was then brought accurately together by thin hare-lip pins, and the operation was concluded. There was very free bleeding from the divided vessels, which was, however, checked by the fingers of an assistant compressing the lip.

In the remarks which Mr. Fergusson made after the operation, he drew the attention of the pupils to the great resemblance between this case and the one which had only a few weeks ago been in the hospital. It was somewhat remarkable that they should have met with two cases close upon each other, as instances of this nature were by no means of common occurrence. He had himself only met with one of the kind previously. A cast of this was shown by Mr. Fergusson. In this case the antrum had been very much dilated, and its anterior wall was, as it were, thrown upwards, so as to form a most remarkable prominence.

In the case where he operated some few weeks ago, they had seen that the antrum had contracted much afterwards, and that there was very little disfigurement when the patient had left,—although, of course, the deformity was not entirely removed. He had performed the same sort of operation in the present instance, but with this addition: he had laid open the soft parts, so as to get freely at the diseased portion. He could no doubt have managed to remove the portion of the front wall of the antrum through the mouth; but it would have been an awkward and troublesome matter, and a most unsightly one. He thought it better in this instance to lay the cheek open, so as to be able fully to expose the expanded bone. They had seen that he had made such an incision as

would leave hardly any deformity behind from the scar. He had merely laid open the upper lip in the mesial line, and had then dissected the parts up from the gums. This was the incision that he preferred in operations upon the upper jaw. The whole of the bone may be removed through this limited incision; but it is one particularly applicable to cases in which there is no necessity to meddle with the upper wall of the antrum. By carrying the external cut through the upper lip, and into the nostril, as he had done in the present instance, the surgeon is enabled to get at the expansion of the jaw without making the very free incisions in the face, which leave behind them very extensive scars.

Correspondence.

THE CASE OF ANNA MERRITT. DR. LETHEBY'S EVIDENCE.

SIR,—When I read the following sentence in the conclusion of Dr. Letheby's letter inserted in the "Medical Times" of March 23rd, 1850, wherein he states—"It is my duty to admit that it is within the range of possibility, nay it is even possible, that the poison (arsenic) might have been taken, as the condemned woman asserts it was taken, early on the morning of her husband's death,"—I thought, on mature reflection, Dr. Letheby had seen his error, and honourably admitted it, and such indeed was, I believe, the general feeling of the medical profession. Had it not been so, I should then have told Dr. Letheby, as I now do, that it was not only Sir Benj. Brodie, Dr. Leeson, and Dr. Ure, who were consulted by the Home Secretary, who disagreed with him, as mentioned by Mr. Bright in the House of Commons, but that several of the first toxicologists of the day did not hesitate to say Dr. Letheby was wrong; and the above retraction only was the cause of my silence. He has, however, again come forward, not in the "Medical Times," where he admitted his error, but in the "Times" newspaper of Monday last, and attacks Mr. Bright, who, in the performance of a public duty, in his speech on the abolition of capital punishments, alluded to Anne Merritt's case, and stated that which was a general impression,—that she was convicted on the rash and unscientific opinion of a medical witness, which was the cause of Mr. Bright's allusion to it as one of the many cases showing the great difficulty of carrying out the sentence of the law after conviction.

In Dr. Letheby's reply to Mr. Bright in the "Times" of Monday last, he repudiates his former admission, and says—"The more

I think over this case, the more I bring it in relation, not only with the results of my own experience, which is not small, but also with the published accounts of other cases,—the more fully am I convinced that my conclusions were founded on facts; that my evidence was the expression of truth: and, since the publication of my letter in the 'Medical Times,' I have not heard one word in opposition to the soundness of my judgment. Therefore, as the opinions on which Sir George Grey acted have not been published, and as none of our toxicologists have even referred to the subject in any of the medical periodicals, with all due deference to Dr. Letheby's vaunted experience, I humbly beg to state the reason why I doubt the soundness of his judgment; feeling deeply the awful consequences which may ensue, in future judicial investigations, if such evidence is admitted in criminal prosecutions.

The question at issue is—How long before death was the arsenic taken? Dr. Letheby, unsupported by any other evidence, circumstantial or otherwise, states, "not more than two or three hours before death;" because he found three-quarters of a pint of undigested gruel in the stomach, which contained $8\frac{1}{2}$ grains of white arsenic, not in a solid state, but in a state of solution. In his letter of March 28d, he asks—Is it probable that a dose of arsenic taken early in the morning would have remained in the stomach for sixteen hours? This is a hypothetical and irrelevant question, because he only found $8\frac{1}{2}$ grains in the stomach; and it is quite consistent with experience that this small residuum of a dose swallowed by the deceased, should have been found in the stomach in spite of all the vomiting, &c.

2. He says, supposing for one moment that such a result could have happened, then the fluids found in the intestines ought to have contained at least as much of the poison as those found in the stomach, after all its retching, vomiting, &c.

Dr. L. seems to forget that in the intestines the poison becomes diffused over a much larger surface, and that it is very frequently carried off by purging, and bases his very strong opinion on the allegation that the eight grains of arsenic which he found in the stomach were really dissolved in a quantity of undigested gruel; but he does not state how he ascertained it was held in solution, and not mechanically diffused as a fine powder in the gruel; nor, in fact, has any proof been adduced, to my satisfaction, that the arsenic was really dissolved; nor has the whole of the arsenic been proved to have been dissolved by any medical fact, to my knowledge. Indeed, I cannot understand how such an inference was arrived at; and, on looking over Dr. Letheby's evidence, I find

he states there was a small portion of a whitish powder adhering to the inner lining of the stomach, but too small a quantity to ascertain what it consisted of: this was no doubt arsenic, and could easily have been proved to be so. This fact renders it probable that all the arsenic was not dissolved, and nothing short of the separation of the $8\frac{1}{2}$ grains which he found in the stomach in a clear solution in water, would have justified Dr. Letheby in making the assertion that the poison was entirely dissolved, and not mechanically diffused as a fine powder through the gruel. It is extremely probable that the gruel taken before death might have become mixed with the poison which had been taken in powder several hours before, and in four or five hours might dissolve a portion of the poison already existing in the stomach at the time it was swallowed: hence, even if a small portion of arsenic was actually proved to have been dissolved, this would not show that the poison must necessarily have been administered in the gruel in from two to three hours before death.

Dr. Letheby concludes there were about two grains of arsenic in the liver, and says—"My observation in reference to the time the poison had been taken, has reference both to the stomach and liver." How this fact would enable him to draw such a conclusion I know not, for I cannot find a single case where two grains of arsenic were found deposited in the liver in either two or three hours; nor have I, on inquiry, found any toxicologist who has met with one.

That arsenic should remain in the stomach even for several days, in spite of copious vomiting, &c., it is not necessary, as Dr. Letheby states, that it should be administered in *large granules*. It so remains in many cases, when taken in fine powder, as in Merritt's case; and if a small quantity, say a few grains, were left adhering to the mucous coat when the gruel was swallowed, this would account for all Dr. Letheby found, without supposing the arsenic was administered dissolved in the gruel, either two or three hours before death, or at any other time. Finally, Dr. Letheby appears to think that gruel, if found undigested in the stomach, must have been taken within two or three hours: this inference, which may apply to healthy digestion, is inapplicable to the case of a person whose stomach is irritated or inflamed by arsenic; and it is quite consistent with experience that the gruel might have been in the stomach for seven or eight hours, and yet not be perfectly digested. The inference, therefore, so far as the undigested state of the gruel is concerned, is not in accordance with physiological facts.

It appears to me that Dr. Letheby has

either committed the great mistake of supposing that gruel taken subsequently to the swallowing of arsenic, cannot mix with or dissolve a very small portion of that poison,—say, as in this case, eight grains to twelve or sixteen ounces of gruel; or he has committed a more serious mistake in inferring that the gruel so taken was necessarily the vehicle in which the poison was administered.

If this reply to Dr. Letheby is not too long for your columns, I shall feel much obliged by its insertion, and am, sir,

Yours most respectfully,
G. B. WADSWORTH.

19, Golden Square,
July 23rd, 1850.

Medical Intelligence.

THE APHLOGISTIC LAMP APPLIED TO ECONOMICAL USE.

THE following suggestion respecting the employment of the aphlogistic lamp for the purpose of procuring heat, was made many years since by Dr. G. Merryweather, of Whitby. As it may be new to some of our readers, we here reprint an extract from a paper which has lately reached us.

"Let the reader imagine a tin lamp of the ordinary form, the cavity of which is filled with strong spirits, instead of oil. A cotton-wick lies among the spirits. One end of it is brought through the orifice or mouth of the lamp in the usual way, and the different threads of which it consists are separated, and spread out a little, so as to leave a sort of cavity in the middle. In this cavity is placed a coil of platina wire, of a cone shape, formed by five or six spiral turns of wire. The wire is about the 100th part of an inch in diameter, and the coil forms a sort of cup, about three-eighths of an inch wide, in the middle of which lies a small piece of *spongy platina*. The lamp being filled with spirits, the wick is to be inflamed: in about a minute the platina becomes red hot; the flame is then blown out, and the glass cover placed over the lamp. The use of this cover is to confine the heat, and prevent all cross currents, so that no air may reach the platina, except what passes in by air-holes below, and escapes by the chimney or opening in the cover above. If the lamp is standing in a chamber somewhat darkened, the platina will now be seen constantly presenting that glowing or incandescent appearance which we observe in red hot iron. The light is strong enough to enable one to see the hour on the dial-plate of a watch at mid-

night, but produces no annoying glare. The spirits are decomposed and fly off, forming, as Dr. Merryweather thinks, water and acetic acid.

"Such is the lamp in its simplest form,—that is, when consisting merely of one burner. If a greater heat is wanted, three, six, or more burners may be placed upon one lamp. In the lamp exhibited to the Royal Society, Dr. Merryweather employed fifteen burners, placed near one another; and with these he maintained a perfectly constant temperature of 396° of Fahrenheit. We call it a lamp; but, when fitted on this scale, a *furnace* is the more appropriate appellation. He was informed that this was a very desirable heat for many chemical or pharmaceutical purposes; but he could, if necessary, raise it to 1000°. He found that the platina wires and sponge undergo no sensible waste, and observes that, by connecting a reservoir of spirits with the cavity of the lamp, the heat might be kept at the same uniform elevation for years. Pure alcohol is not necessary. He finds that whiskey, 22 per cent. over proof, 9s. per gallon, answers perfectly well. With fifteen burners, producing a temperature of 396°, the quantity of spirits consumed in twelve hours costs 1s. 3d.; with three burners, yielding a heat of 160°, the cost is 3d., which is not great, if compared with the expense of attendance when the same object is obtained by means of common fuel. It may be proper to mention, that the glass cover placed over the lamp with fifteen burners was a cylinder about seven or eight inches wide, and ten or twelve inches high; and the heat alluded to was kept up within a space of this extent, which was empty, and of course available for experiments."

CHOLERA AT MALTA.

LETTERS from Malta of the 22d instant state that the cholera was still prevailing there; and, though the cases were not quite so numerous, the mortality was as great as ever. The men and women of the 44th Regiment still suffered, and, unfortunately, not one attacked has been saved. The fleet was still cruising on and off the island, daily communications being kept up by boats. The amount of deaths in the fleet was small compared to those on shore, only 14 having occurred out of more than 300 cases.

THE CHOLERA IN MEXICO.

LETTERS from Vera Cruz, *via* New Orleans, dated the 1st instant, announce that the cholera was devastating the capital. From May 17th to June 16th several hundreds had died. At St. Luis Potosi also the disease prevailed.

COLNEY HATCH LUNATIC ASYLUM.

DR. J. D. DAVEY, formerly one of the physicians of the Hanwell Lunatic Asylum, has been appointed one of the resident physicians at the Colney Hatch Asylum. Dr. Hood is to be Dr. Davey's colleague.

MEDICAL BELIEF IN IRELAND.

THE total number of dispensaries in Ireland is 660; fever hospitals, 63; and Infirmarys, 41. The presentments made for their maintenance in 1849 were £78,011. 18s. 5d.; and the subscriptions amounted to £29,470, 18s., making a total of £107,482. 18s. 5d.

THE JACKSONIAN PRIZE.

THE following subject has been announced by the Council of the Royal College of Surgeons for this prize, for the ensuing year:—"The Causes, Diagnosis, and Treatment of Obstructions of the Intestines."

CASE OF PROFESSOR WEBSTER.

AFTER a hearing before the full bench of the supreme Judicial Court, upon the application for a writ of error, in the case of Dr. Webster, the judges have decided that their former proceedings were strictly legal, and in conformity to the statute; and the application was therefore dismissed. It is expected that the Governor and Council, with whom the whole matter now rests, will act upon his case in a few weeks.—*Boston Medical Journal.*

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 26th inst.:—Messrs. C. A. Newnham—F. Martin—W. Cockcroft—H. W. Lobb—A. Kitching—C. O. Rowley—J. A. Cox—E. W. S. Davis—G. G. L. Williams—S. A. Chaldecott.

Admitted on the 30th inst.:—Messrs. W. Bourne—T. D. Everet—G. S. Rhodes—J. W. Beaumont—J. Marriott—T. Brown—J. P. Scowcroft—R. E. Fitzgibbon.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practice, on Thursday, 26th July, 1850:—George William Pettinger, Sutton-upon-Trent, Notts—Henry Goode Wright, Hereford—Thomas Carey, Midhurst, Sussex—William Helps, Gloucester—Harry William Lobb, Southampton—John Kenyon Wright, Stockport, Cheshire—Frederick Hudson, Stockport, Cheshire—Francis Godrich.

OBITUARY.

On the 25th instant, at Hampstead, Middlesex, aged 73, Mr. Thomas Davis, surgeon.

At Bombay, of malignant cholera, Dr.

Larkworthy. This gentleman was cut off by the disease during his active attendance on the sick.

On the 30th ult., John Miles, Esq., surgeon, 78, Gracechurch Street, deeply lamented by all who knew him.

Selections from Journals.

ON THE PRESERVATION OF THE BODY IN CASES OF ARSENICAL POISONING. BY T. G. GEOGHEGAN, M.D., DUBLIN.

[Concluded from p. 175.]

In the judicial examination of cases of arsenical poisoning, much attention has been excited of late years by the singular condition of *preservation* in which the digestive tube and (in some cases) the entire body has been discovered at comparatively remote periods after death. As such inquiries are of some importance to the practitioner in the exercise of his medico-legal functions, I shall proceed to relate the observations which I have been enabled to make.

A. In the cases in which the *whole body* has been the subject of inspection, the following conditions have been noted:—

1st. Complete preservation of the body and viscera (during periods of observation of from sixty-three to seventy-two hours) under circumstances *highly favourable* to putrefaction.

2d. Rapid putrescence of body and viscera (under conditions extremely adverse to decomposition). This occurred in the case of an individual who fell a victim to the accidental administration of arsenic after an illness of thirty-six hours. The weather at the time was decidedly cool; the subcutaneous cellular membrane, notwithstanding, was emphysematous (from putrefaction) twenty-two hours after death; and the intestinal canal, in eight hours more, was much advanced in decomposition, of a dark green colour, and rapidly evolving gases of extreme fætor.

3d. Good preservation of stomach and intestines; the body decaying as usual (at periods of forty-seven and seventy-five days after death, the illness having been of eleven days duration).

4th. Rapid decomposition of the alimentary canal; the body remaining unaffected. (Examination thirty-four hours after death; illness of fourteen days.)

B. *The digestive tube*, or parts of it (removed from the body), has exhibited the undermentioned phenomena.

1st. Almost complete preservation of stomach (emptied of its contents) during

four weeks, followed by modified decay during eight weeks, with neutral state of tissue, and termination in ammoniacal decomposition. The case to which this observation refers is that recorded in the first part of this paper. The poison appeared to be altogether in solution, and when modified decay commenced, the surface of the organ became coated with a pulpy matter. The morbid appearances, however, remained little altered. At this date (thirteen weeks after death), the black extravasation is quite distinct, the walls of the organ firm on traction, and the peritoneal surface retentive of its lustre. The odour is different from that of common putrefaction.

2d. *Rancid putrefaction*.—I venture to apply this designation to a singular condition which I believe to have been not hitherto described, and which I have witnessed in at least three cases. It is characterized by a *peculiar odour* (somewhat like that of fatty matter when undergoing slow decomposition), and by a *persistent and strong acid reaction*, which, in a stomach still under observation, has been retained undiminished during more than three years and a half. I have found in these cases that the tissues retain their physical characters and morbid appearances unimpaired for some weeks, but finally become softened and discoloured. The absence of ordinary ammoniacal putrefaction is not confined to cases in which death has been produced by arsenical poison. I have found a stomach, which contained a quantity of vegetable matter (apparently apples), undergo the *acetous fermentation* in its tissues, and retain it (although frequently washed) for several months. It is still more singular that a fluid so prone to decomposition as urine, is occasionally imputrescible. Thus I have had a specimen (containing abundance of urea) which remained perfectly fresh for years, although kept in a vessel by no means air-tight. It perhaps included more saline matter than usual. I have observed much retarded putrescence in some other specimens.

In arsenical poisoning, as sometimes happens in other forms of death, the decay of the alimentary canal is not equal throughout: thus in a case (fatal in less than a day) the intestines commenced to putrefy twenty-four hours after death (in cold weather), and on the third day the osæum was advanced in putrefaction, the stomach remaining unchanged—a circumstance perhaps due in that instance to the presence of free æsæic on parts of its surface; yet the uterus and a portion of muscle which could have only contained the small quantity of poison that reached them through the blood, were quite fresh on the fifth day.

In comparing, however, the preservation of different organs, due allowance should be made for diversity of tissue. A careful examination of the cases which have occurred in my experience has led me to the belief that, with the exception possibly of those instances in which the poison in quantity is in direct contact with an organ (*e. g.*, the stomach), *the preservation of structures, or the contrary, is not influenced by its presence or absence in their tissue*. Thus I have found arsenic absent in the membranes of a stomach, which, after an inhumation of forty-seven days, was in a state of considerable preservation, and the great intestine, which afforded not more than one-twentieth of a grain of arsenic, was in an equal state of integrity after seventy-five days. Arsenic was discovered freely in the liver, which was less preserved.* On the other hand, in recorded cases, in which the whole body has putrefied rapidly, the presence of the poison has been indicated in the fluids and tissues, either by chemical examination or (as in a case which I have witnessed) by the short duration of the illness having been incompatible with the elimination of the portion absorbed. The quantity of the latter, moreover, even in those organs which appropriate the greatest amount (*e. g.*, the liver), is absolutely small; not perhaps exceeding, on an average, from one and a half to two grains; and hence incapable of effecting their preservation by direct chemical union. I have been hence led to infer, that arsenic, in most cases, produces its antiseptic effects, local or general, by means of a *catalytic* or disposing influence, in virtue of which such changes are produced, either in the molecular condition of the tissues, or in the atomic grouping of their ultimate elements, as confers on them a character of unusual stability.

In concluding this notice of the post-mortem changes in arsenical deaths, I wish to allude to the alleged evolution of an *alliacæous odour* during the decay of the body. Although I have not met with this condition in the body at large, I have perceived it most distinctly during the slow decay of organs which have received the poison by absorption—as the liver. I have no doubt that it is due to the evolution of arseniuretted hydrogen.†

* In this case, although the patient survived eleven days, the poison seemed present in as great quantity in the liver as I have found it in others which were fatal in a few hours. In another instance, I detected the poison in the same quarter after an illness of fourteen days. It was, however, in much less quantity than usual.

† It was curious to observe that numerous minute insects which had attacked fragments of these organs (contained in a closed vessel), seemed in no wise incommoded by the atmosphere in which they were placed.

Some of the facts already cited, in association with a variety of others, are, I conceive, incompatible with the hypothesis offered by Liebig, as explanatory of the *modus operandi* of various mineral poisons (arsenic included), which assumes their deadly action to be due to a chemical union with the tissue of the different organs, and consequent arrest of those vital transformations within them which are essential to the performance of their functions. That chemical combination of the poison with the tissues takes place, I have satisfied myself with respect to the liver. The liver of a patient poisoned by arsenic (the organ having been divided into small fragments) was macerated in successive portions of distilled water, till all the blood and soluble matters were extracted; almost the entire of the poison was found in the insoluble residuary tissue. We are not, however, from hence legitimately entitled to infer, that such union is the cause of the usual symptomatic manifestations, and for the following reasons:—

1st. The quantity of the organic tissue involved in such combination (compared with the mass of the organ) is excessively small, as already shown. Were the quantity of absorbed poison sufficient to chemically saturate the proximate principles of our organs, the latter should in *all* fatal cases be imputrescible, which is contrary to experience. It is remarkable that, in poisoning by corrosive sublimate, which has such a powerful affinity for animal matters, the preservation even of the digestive organs is not effected by it, except at those points of the mucous membrane corroded by its direct contact: such, at least, is the result of my experience.

2d. The lesion of function is often inversely as the amount of poison contained in the tissue (as in the liver, muscular system, &c., compared with the brain and heart).

3d. Life is often compromised in cases where the entire of the compound, which may have been formed by the union of the poison with the tissues, has been eliminated by the excretory organs.

The foregoing considerations, together with the rapid disappearance of poisons from the blood,* lead to the inference that

* In a case of poisoning by acetate of lead, in which two drachms were administered twelve hours before death, I was unable to detect a trace of the poison in the blood collected from the heart, although the heart itself gave indications of its presence; while in the liver, kidneys, lung, and tissue of the intestine, it was readily discovered. The deposit of poison in the osseous system has been interestingly shown in some recent cases of arsenical poisoning. From this system, however, it is ultimately eliminated; thus I could not discover any trace in a portion of the femur of a girl who died on the fourteenth

the depositions of the latter in the tissue of the secretory organs and in the muscular and osseous systems, so far from being the cause of the formidable manifestations observed, is, on the contrary, a beautiful provision for the allocation of those substances in parts in which their presence is productive of the least disturbance. Even in the now advanced state of physiological knowledge, it must be confessed that, however definite our conceptions may be of the local action, absorption, circulation, distribution, and final elimination of poisons, the intimate nature of their influence on remote organs has yet to be determined. Thus, notwithstanding the ingenuity of modern theorists, we are still ignorant of the precise *modus operandi* of strychnia on the spinal cord, of tobacco or arsenic on the heart, or of opium on the brain.

There seems, meanwhile, to be little reason to doubt that arsenenic acid produces a profound disturbance in the molecular constitution of the blood—a disturbance which perhaps (through the agency of operations to be hereafter discovered) influences certain classes of vessels, while others remain exempt. It may be also readily conceived that such disturbance may be perpetuated after the withdrawal of the exciting cause, and that hence an explanation may be afforded of the occasionally fatal effects of poisons at periods posterior to their separation from the blood, or their final elimination from the system.

The late experimental investigations of Dr. Blake, and of Frierichs and Wöhler, as to the absolute or comparative innocuity of arsenic acid (which is isomorphous with, and hence capable of replacing the phosphoric acid of the blood, without subversion of the molecular constitution of that fluid), and the harmless nature of that singular organic compound of arsenic, the cacodylic acid, afford some countenance to the views above stated, which I desire to be considered in the light of suggestions only.

CHOLERA PRODUCED BY EFFLUVIA FROM THE DEAD.—BY DR. REEB, U. S.

DURING the epidemic by which our city and its vicinity so severely suffered, there were but very few cases at Bellevue, notwithstanding the large number of patients here, and of a class signally predisposed to become its victims. The preventive measures relied on were a strict attention to cleanliness in and about the entire

day, although I found it in the liver. The recent researches of M. Millon (*Annales de Chimie*) on antimony, demonstrate that the latter substance remains (in some cases of tartar emetic poisoning) in the structure of the bones for several weeks, and also occasionally in the subcutaneous fat. I searched for arsenic in the latter quarter in the above case without success.

premises; thorough and persevering ventilation of all the wards; the extensive use of ice and iced water; and a careful regulation of the dietary habits of all the inmates. Good dry sugar was at once substituted for molasses, and better supplies of food, both in quantity and quality, were forthwith provided. Very little medication of any kind was permitted, and all cathartics were forbidden. When the premonitory diarrhoea began to exhibit itself, it was made the duty of the orderly or nurse of every ward to notify the assistant-physicians of every instance in which looseness of the bowels was observed; and, at stated hours, a medical inspection of all the patients was made both day and night to detect the earliest symptoms, which there was a disposition to conceal. The prescribed antidotes were placed in every ward, to be in readiness at all times; and all the inmates were instructed in the importance of early treatment in case of an attack.

For several weeks, and even after the neighbouring institutions in Blackwell's Island were visited with the epidemic, the hospital at Bellevue had wholly escaped; nor is it probable that we should have had a single case had not the atmosphere of the entire premises been rendered impure and offensive to the last degree by the contents of the dead-house for the whole city, which is most improvidently located within a few yards of the hospital. At the climax of the epidemic, more than a hundred bodies were deposited here in a single day, whence they were to be transported in boats to "Potter's Field;" but the means of removal being inadequately provided, they were allowed to accumulate; and the effluvia became so offensive, that it was necessary to close all the windows opening towards the dead-house; and even then the stench was intolerable. All ventilation of the wards being thus precluded, one, and then another, case of cholera began to appear, and the premonitory diarrhoea now became almost universal throughout the house, a score or more being thus seized in a single night.

It was not until a number of deaths had occurred, including the keeper of the dead-house, and the gate-keeper who was located near it, that our remonstrances were heard; and the necessary provision to empty the dead-house, by removing the bodies every evening, could only then be obtained. From that time the cases were few, and occurred at intervals of several days, so that all apprehensions of its becoming epidemic here were at an end. The whole number of cases during the summer did not exceed thirty, and several of these were brought hither. The persons attacked were chiefly broken down previously by age, intempe-

rance, or chronic disease of long standing, so that a majority of all the collapsed cases were fatal. Several of them had no premonitory symptoms whatever, while others concealed their symptoms until in a hopeless condition. The few recoveries were in persons who were treated internally by large doses of calomel, repeated every two or three hours, varying from ten to twenty grains, and usually in combination with capsicum, or camphor, or both; large quantities of ice were eaten meanwhile, and the surface of the body covered with heat and stimulants. In other cases, however, it must be conceded that this identical treatment failed; but without it none recovered. A slight pyralism followed in three cases, one of which afterwards died of consecutive fever. Only two of our cases were bled, and one of these recovered. I have notes of all the cases, numbering twenty-nine, of whom eight only were saved.

Our success in arresting the diarrhoea was very nearly universal; and, indeed, only one case of death occurred when the premonitory symptoms were discovered. There was no novelty in the treatment of these, our reliance being chiefly on rest, ice internally, with heat to the skin, and an occasional dose of ether, *sp. lavend. c.*, and vinum opii, mixed in suitable proportions, which was found sufficiently astringent, cordial, and anodyne for our purpose. The tinct. capsicum was occasionally tried in various combinations, but was found to offend the stomach, so that even landanum was rejected when mixed with it, and retained only when given alone.

Whole number of cases from June		
10th to July 26th	137	
" " recoveries	47	
" " deaths	90	
Rate of mortality, 67 per cent.		

—*American Journ. of Med. Sciences*, 1850.

CARIES OF THE CRANIUM.

A WOMAN, sixty-three years of age, suffered from caries of the cranial bones, the consequence of syphilis. The upper and under surface of the bone was deeply furrowed, as if worm-eaten, and the os frontis was perforated. The diploë was thickened and indurated. On the inner surface of the bone there was seen an exostosis—the *osteophyte* of Rokitsansky. This patient had probably formerly been the subject of rickets.—*Casper's Wochenschrift*. X

RELATIONS BETWEEN ANGINA PECTORIS AND ASTHMA.

THE intimate relations between asthma and angina seem to have been perceived by most writers on the latter, as the diagnostic marks of both have been given together.

Darwin has given angina the name of painful asthma.

Both come on by sudden paroxysms, at irregular intervals. In both there is a sense of painful constriction and suffocation, of epigastric tension with eructations, yawning, coldness and paleness of the face, the pulse comparatively unaffected, difficulty of speaking, the health good in the intervals, until the arrival of secondary causes of dyspnea (usually emphysema, or other symptomatic asthma). Both are alike brought on and influenced by atmospheric changes; by the action of a cold dry wind; by mental emotions; perhaps also by hereditary predisposition. Both have been ascribed to the same lesions of the respiratory and circulating systems, even to ossification of the costal cartilages, coronary arteries, and cardiac valves: both are relieved by the same treatment, narcotics, antispasmodics, and revulsives. Many cases of angina are recorded in which symptoms of asthma first appeared, and disappeared in the course of the disease: viz., fits of nightly suffocation, after the first sleep, which compelled the patient to fly to an open window for relief.

The differences between angina and asthma may be explained by the different functions of the filaments of sensation and motion in the par vagum. In asthma the dyspnea is more characteristic than pain; every muscular power is brought into action to introduce air into the lungs; the diaphragm and pectorals contract convulsively; the desire for air is extreme, and the patient seems continually on the point of suffocation. During the paroxysm there is more or less absence of the respiratory sounds, from the difficulty the air finds in entering the pulmonary vessels; hence the violent and noisy laryngeal respirations. When the fit ceases there is copious expectoration, with mucous râles, and cough. The muscular fibres of the bronchi and their ramifications are animated by the spinal accessory nerve; the dyspnea of asthma depends on the spasmodic contraction of these fibres, the partial obliteration of the air-passages requiring violent respiratory efforts to secure the necessary introduction of air; in this constriction the larynx is involved, as evinced by the whistling of the inspirations; the non-introduction of air into the pulmonary vesicles accounts also for the diminution or even absence of the respiratory murmur.—*Dr. Kneeland; in American Journal of Medical Sciences, 1850.*

BOOKS & PERIODICALS RECEIVED FOR REVIEW,

REMARKS.—The total number of deaths was 723 below the average mortality of the 30th week of 44 previous years, although 55 above the mortality of the preceding week. The deaths from diarrhoea have undergone a great increase; but of the 104 recorded, 84 occurred in infants under 1 year, and 6 among persons above 40. Of the 13 deaths from cholera, 3 are marked as "Asiatic." The deaths from this disease were not, however, so numerous by one-half as in the corresponding week of 1846.

METEOROLOGICAL SUMMARY.

Mean Height of the Barometer.....	29.49
Thermometer.....	63.4
Self-registering do.	Max. 59° Min. 63°
From 12 observations daily. Sun.	

RAIN, in inches, 0.83.—Sum of the daily observations taken at 9 o'clock.

METEOROLOGICAL.—The mean temperature of the week was 2.4° above the mean of the month. The week was chiefly remarkable for the quantity of rain which fell.

NOTICES TO CORRESPONDENTS.

Dr. A. H. Hassall.—We much regret that, owing to the length of the extract accompanying it, we cannot find room for the letter this week. It shall appear in the following number.

The papers of Dr. E. J. Tilt, Mr. Jennette, Mr. S. Bate, and Mr. Grantham, with the letter of Mr. R. H. A. Hunter, next week.

The valuable communication of Mr. Pearson and Dr. Curtis, on the Poisonous Properties of Lobelia inflata, stands next for insertion.

Dr. Snow's paper on Chloroform has been received.

Mr. Kodalle's contribution on Mesmeric Operations will be inserted.

Lectures.

COURSE OF LECTURES
ON
DISEASES OF THE HEART.

*Delivered at St. Vincent's Hospital during the
Session 1849-50.*

By O'BRYEN BELLINGHAM, M.D.

Fellow of, and Member of the Court of Examiners
of, the Royal College of Surgeons in Ireland, and
one of the Medical Officers of the Hospital.

LECTURE IX.

EXAMINATION OF THE HEART IN DISEASE,
CONTINUED.

Signs furnished by Auscultation—Alterations in the intensity and tone of the sounds of the heart—Alterations in the duration of the sounds of the heart—Alterations in the limits within which the sounds of the heart are audible—Alterations in the frequency of the sounds of the heart—Alterations in the rhythm of the heart's sounds—Alterations in the number of the heart's sounds.

Signs furnished by Auscultation.

AUSCULTATION, like percussion, may be either immediate or mediate. Although immediate auscultation is preferred by some, there are several objections to it. Thus, in the case of females it is indelicate; in dirty persons it is disagreeable; while in contagious diseases it is not without risk: besides, there are some situations in which either the ear cannot be applied, or in which the stethoscope is much more convenient. In examining the præcordial region in cases of valvular disease, or where there is a suspicion of it, mediate is always to be preferred to immediate auscultation: indeed, the exact situation, or the limits of an abnormal sound, can in the majority of cases be satisfactorily determined only by the assistance of the stethoscope.

As the sounds heard in a healthy state of the heart must be the standard of comparison in judging abnormal sounds, it is of course necessary to be familiar with them before commencing the examination of cases of disease; yet this is a matter frequently overlooked by the student. He begins by examining the cases of disease of the heart which come under his observation in hospital, without, perhaps, any previous knowledge of its normal sounds. Now it is scarcely necessary to observe that, unless the character, duration, intensity, and other qualities of the normal sounds of the heart, are known, the student is not in a condi-

tion to appreciate the numerous modifications or alterations which these sounds undergo in disease. It would, in fact, be almost as reasonable to commence the study of anatomy by entering at once on pathology, without any knowledge of the healthy appearance of the organs, as to commence the practice of auscultation by examining cases of disease.

In cases where the heart is diseased, or suspected to be so, it is often advisable, before concluding the examination, to make the patient walk quickly up and down stairs, or backward and forward in the room, with the view of accelerating the circulation and increasing the heart's action; by which, abnormal sounds will be often rendered more evident, or a murmur which was inaudible previously may become distinct. Thus, a musical murmur is sometimes audible at the mitral orifice only, when the action of the heart is increased by exercise, a simple bruit de soufflet replacing it as the circulation becomes tranquil. When a murmur, which was inaudible as long as the circulation was tranquil, becomes evident when the heart's action is increased, it is highly probable that there is, as Dr. Latham* observes, "a mechanical obstacle at an orifice of the heart, but that it is of small amount, not enough to cause the requisite degree of vibration when the current of the blood is slow and undisturbed, but quite enough when it is more rapid and forcible."

Again, in some cases it may be necessary to examine the patient in the sitting or erect as well as in the recumbent position, or to make him lean forwards. Thus, in a case of pericarditis which we had in the hospital, the friction-sound at one period became nearly inaudible in the recumbent posture, although sufficiently evident in the sitting posture, and still more so when the patient leaned forward. Or the friction-sound may diminish in intensity in the sitting posture, and become well marked in the recumbent position; obviously depending on the difference in the situation in which the lymph has been deposited.

It may, in addition, be sometimes necessary to make the patient hold his breath for a few seconds at a time during the examination, particularly if a murmur is not well marked, or if the auscultator is inexperienced, or if the sonorous or sibillant râles of bronchitis are loud. Lastly, if any difficulty should be experienced in distinguishing between the first and the second sound, or in determining to which a murmur should be referred, the finger ought to be kept on the radial pulse, or, better still, upon the carotid artery, during the exami-

* Lectures on Diseases of the Heart, vol. i.

nation; and the stethoscope should be applied on the right side of the sternum, and the sounds of the right cavities traced towards the left side.

Ismaeac has made the remark that, when a portion of lung is interposed between an enlarged heart and the parietes of the chest, the impulse of the organ, by compressing the lung and expelling the air from it, may give rise to an abnormal sound resembling some of those heard in cases of disease of the heart. "A strong impulse of the heart on a portion of lung may (as Dr. Williams* observes) forcibly press the air from it; and, if there happen to be any partial obstruction or mucus in its tubes, a short sibilant or mucous rhoncus may accompany each beat." "The character of these additions, and the circumstance that they accompany this breathing also, and are more or less diminished by holding the breath, or by posture altering the manner in which the heart beats on the lung, may serve to distinguish them from the true cardiac sounds."

Again, it sometimes happens in the advanced stage of phthisis that each impulse of the heart is accompanied by a tinkling sound, resembling the tintement métallique. This occurs in cases in which a large tubercular cavity, or two or more cavities communicating with one another, containing a certain amount of fluid, occupy the greater portion of the upper lobe of the left lung, its lower lobe being at the same time solidified by tubercular deposition, and when the action of the heart is strong. The sound here may accompany both the impulse of the heart and the respiratory movements. In a case which was in the hospital some time since (where this abnormal sound was sufficiently loud to be audible without applying the stethoscope, and at some distance from the patient's bed), it accompanied only the impulse of the heart—not the respiration, during a portion of the time that the patient was under observation.

In diseased states of the heart, its valves, or orifices, the sounds are variously modified or altered. Thus, in some instances, their intensity is greater or less than natural; in others their character or tone is altered; and in others their duration is affected. Sometimes the extent of surface over which they are heard is increased or diminished, or they may become more frequent, sometimes less frequent than natural; or their rhythm may be variously disturbed. Lastly, and in a very numerous class of cases, new sounds are superadded, which either accompany the normal sounds or take their place.

Alterations in the intensity and tone of the sounds of the heart.—The intensity of the heart's sounds varies in different individuals, and under different circumstances: varieties are likewise met with in the character of its sounds, some of which are observed in cases of disease, while others occur independently of any morbid change in the heart. Thus, in persons in whom the parietes of the thorax are loaded with much fat, or where these parts are cedematous,—in muscular subjects in whom the chest is largely developed, and whose lungs are ample,—the sounds of the heart have less intensity than in individuals in whom the chest is narrow or deformed, in whom its coverings are thin, or in whom the cartilages of the ribs are ossified. Whenever, likewise, the energy of the heart's action is increased, the sounds, as a general rule, become loud. Thus, in nervous and hysterical subjects,—in palpitation from any cause, under the influence of mental emotion, or after exercise,—its sounds become more intense than natural. On the other hand, when the energy of the heart's contraction is lessened from any cause, the intensity of the sounds will be diminished.

The intensity or the tone of the sounds of the heart is frequently modified by disease; but this applies more particularly to the first than to the second sound: thus, when the walls of the ventricles are hypertrophied, the first sound becomes more obtuse, or duller than natural;—when the cavity of the ventricles is dilated, the first sound is said to become clearer than natural;—when the walls of the ventricles are attenuated, combined with dilatation of their cavities, the first sound somewhat resembles the normal second sound, while the second sound is feeble;—when the muscular tissue of the heart is flabby or softened, both sounds become more feeble and obscure, besides undergoing other changes afterwards to be mentioned. In the advanced stage of fever accompanied by considerable debility, the sounds of the heart sometimes become extremely feeble; during the state of syncope, also, its sounds are feeble and indistinct, and the second sound is often inaudible. In dilatation combined with some hypertrophy of the ventricles, both sounds are loud; when, however, the hypertrophy predominates over the dilatation, and this diseased state has arrived at an extreme degree, both sounds, but particularly the first, become obscure.

Clearness of the first sound of the heart is very generally considered to be an indication of dilatation of the ventricles; this, however, must be taken with some limitation, for this character of the first sound is often observed when the cavity of

* On Diseases of the Chest.

the ventricles is not dilated, as well as in cases where the parietes of the ventricles are considerably hypertrophied. Dr. Olendinning* says he has found the first sound of the heart to be abnormally short, shrill, and clear, approaching the character of the normal second sound in numberless instances, in hearts proved post-mortem to be much and even enormously hypertrophied. According to him, "a short, clear, systolic sound indicates not so much any particular anatomical state of the heart; but rather a defective dynamic condition; that it indicates, in a word, not *attenuation* of the parietes, but merely *debility*." M. Piorry likewise attributes little importance to difference in the clearness of tone of the sounds of the heart, as a sign of hypertrophy or dilatation of the ventricles. He says he has "frequently found the parietes thickened when the sound was clear, and vice versa, and the tone frequently varies in the same person if subject to palpitation." He attributes clearness of tone to the amount of blood contained in the cavity, the sound being clearest when the heart is most empty, yet is contracting with energy, as in palpitation.

Alterations in the duration of the sounds of the Heart.—The sounds of the heart are modified or altered in their duration as well as in their intensity in some diseased states of the organ. Thus, in hypertrophy of the walls of the ventricles, the first sound is more prolonged than natural; in dilatation of the ventricles, the first sound is shorter than natural. "The transition of a thick muscle from slack to tight can never be so complete and sudden, Dr. Williams† observes, as that of a thin one; where there are many fibres, they cloke and muffle each other's vibrations, hence the first sound is dull and prolonged;—a thin ventricle, for the same reason, will give a louder and sharper sound." But if a thick ventricle takes a longer time to contract upon its contents than a thin ventricle, the blood must obviously pass out of the cavity more slowly in the former than in the latter; and as sound appears to be produced during the entire period that the blood is being transmitted from the ventricle, the first sound must necessarily be prolonged in this diseased state.

Alterations in the limits within which the sounds of the heart are audible.—The extent of surface over which the sounds of the heart are audible on auscultation in the healthy and well-formed chest, is not great, being pretty nearly limited to the

præcordial region, and as the stethoscope is moved from this part they become more and more indistinct. There is, however, considerable difference in this respect, in different subjects; in individuals whose chest is covered with much fat, and in whom the impulse is slight, or hardly perceptible, the sounds are more limited; while in thin subjects, in persons with narrow chests, in children and females, in individuals whose chest is contracted and deformed, and in nervous subjects, the sounds are audible over a wider area. The sounds produced at the right side of the heart are more perceptible upon the right side of the præcordial region, while those produced in the left cavities are more distinct at the left side of this region. When the sternum is short the sounds of the heart are often audible likewise in the epigastric region.

In several diseased states of the heart or of the lungs, the sounds become audible over the greater part of the anterior surface of the chest, and sometimes in addition in the lateral and posterior regions upon both sides: while in other morbid states the sounds are very obscure, even in the præcordial region. Whenever the intensity of the sounds is increased, or whenever the heart itself is enlarged, its sounds, as might be expected, are audible beyond their normal limits, provided the circulation through the heart and lungs continues free; hence in dilatation of the ventricles, and in dilatation combined with hypertrophy, the sounds are widely diffused. In palpitation from any cause, particularly in anæmic, nervous, and hysterical individuals, the sounds of the heart will be heard over great part of the anterior surface of the chest, particularly if the subject is emaciated.

The sounds of the heart, however, frequently become audible on auscultation beyond their normal limits, even over the greater portion of the chest, independent of any alteration of the heart. This happens whenever the density of the pulmonary tissue is increased, by which its power of conducting sound is augmented; hence, in solidification of the lungs from hepatisation, from tubercular deposition, or from any other cause, the sounds of the heart will be audible to a considerable distance beyond the natural limits of the præcordial region; and this very extension of the heart's sounds becomes a useful sign in some diseases of the lungs. In displacement of the heart the situation at which the sounds are heard will be of course altered; but, as the seat of the impulse is likewise changed in such cases, it need not be dwelt upon here. A large amount of fluid in the pericardium, or an emphyse-

* Croonian Lectures, Med. Gaz. vol. xxv.

† On Diseases of the Chest.

matous condition of the margin of the lungs, might prevent the sounds of the heart from reaching the ear; but there are other signs by which these diseased states may be more readily diagnosed.

Alterations in the frequency of the sounds of the heart.—The sounds of the heart may be more frequent than natural, or they may become slower than natural, or they may be intermittent or irregular. They are more frequent than natural in all inflammatory affections of the heart or its coverings, as well as in numerous diseases of other parts, in states of debility, in cases of anæmia, or whenever palpitation arises, whatever be its cause. The heart's sounds much less frequently become slower than natural; when they do, the cause lies more frequently in disease of the nervous centres than of the heart. Fatty degeneration has been supposed by some to cause a diminution in the frequency of the heart's action. That it does so appears to me to be doubtful. When slowness of the pulse has accompanied this diseased state it probably depended upon idiosyncrasy, or some other cause. In hypertrophy of the ventricles the heart's action is sometimes slow. It is not, however, an ordinary occurrence, because, although the first sound is more prolonged than natural, the interval of repose is usually shortened in proportion. Dr. Willis* observes that, when considerable contraction of the aortic orifice exists, the pulse becomes much slower than natural: "here the ventricle, engaged in squeezing its charge through a hole little or no larger than a goose-quill, perhaps, has been found contracting with no greater frequency than twenty-five, twenty, and even sixteen times in a minute." It is not easy to understand how contraction of the aortic orifice can render the action of the heart slow, although it may, no doubt, considerably diminish the amount of blood transmitted at each systole of the ventricle.

Alterations in the rhythm of the heart's sounds.—In all the cases which we have been hitherto considering, whether the sounds of the heart were increased or diminished in intensity, whether they were more frequent or slower than natural, the rhythm of the organ was regular; the two sounds succeeded one another, and were followed by an interval of repose, which varied in length according to the duration of the previous systole, and according to the rapidity with which the sounds succeeded each other. It not unfrequently happens, however, that after a certain number of perfectly regular beats, a sudden

pause or silence occurs; the heart's action and sounds appear to be arrested or suspended for a moment, and then go on regularly, as before, when, after a certain number of beats, the same phenomenon is repeated. This constitutes intermittence or intermission of the heart's action; and it may occur after every fourth, eighth, or tenth beat, or at longer or irregular intervals. It is occasionally observed in individuals who are otherwise in perfect health: but it also occurs in diseased states of the valves or orifices of the heart, where either some impediment exists to the direct passage of the blood, or where regurgitation is permitted.

In the ordinary theory of the mechanism of the heart's sounds intermission is with difficulty explained; but if it be admitted that the sounds of the heart have their cause in friction between the blood and the parietes of the orifices of the heart, we can easily understand how, in certain diseased states, so little blood may be expelled from the left ventricle; or it may be propelled with so little force that there is not friction sufficient to generate a sound, or force enough to produce an impulse, or to communicate a pulse to the radial artery. We know that the circulation may go on when the sounds of the heart are scarcely audible, and when no impulse can be felt in the præcordial region, as in syncope; yet, in such cases, the valves must perform their functions, and the muscular walls of the ventricles contract and dilate.

It sometimes happens that every systole of the left ventricle is not sufficiently strong, or the amount of blood transmitted by the left ventricle is not sufficiently great to communicate an impulse to the radial artery, and the pulse intermits: but, on applying the stethoscope to the præcordial region, the sounds are still heard, although more feebly, and there is no real intermission of the heart's action. If this should occur at every second ventricular systole, the pulse will appear to be preternaturally slow: and this probably is the true explanation of some of the cases of slow pulse which have been recorded. The error would have been corrected by applying the stethoscope to the præcordial region.

In certain diseased states of the muscular tissue of the heart, of its valves, or orifices, the rhythm of the heart's sounds undergoes still further alteration: the relative duration of the sounds to the interval of repose is altered, the latter being increased or diminished; while the double sound of the heart is rapidly repeated twice or thrice, followed by two or three slower repetitions of the same sounds, some of the sounds being strong, others weak (particu-

* MEDICAL GAZETTE, VOL. I. 1842-43.

larly the second sound, which is sometimes imperceptible), and accompanied by occasional intermissions. The rhythm of the heart's sounds is then said to be *irregular*. This is observed in cases where the ventricles become overloaded or over-distended with blood, which they are unable to expel; and where, consequently, the circulation through the heart or lungs, or through both, is impeded. It is observed in the advanced stage of several diseases of the heart, as in considerable contraction of the mitral orifice, in softening of the muscular tissue of the ventricles, in pericarditis with copious liquid effusion; or where polypiform concretions are developed in the cavities of the heart previous to death. It is of course a much more unfavourable symptom than simple intermission.

Alterations in the number of the heart's sounds.—Another alteration in the rhythm of the heart's sounds, occasionally observed in cases of disease, is where, instead of the ordinary double sound, we have a triple sound, as if each systolic sound was repeated twice for one diastolic sound, or each diastolic sound was repeated more than once for one systolic sound. In other cases both the systolic and diastolic sounds appear to be doubled, and four sounds are heard for one impulse of the heart. Lastly, it sometimes happens that only one sound is audible, in place of the ordinary double sound, and it is then always the second sound which is absent.

When we hear a triple sound in place of the ordinary double sound of the heart, it is more frequently owing to a reduplication of the systolic than of the diastolic sound. This reduplication of the first sound is compared by M. Bouillaud to the tattoo of the drum: it more nearly resembles what is called in Ireland "the Kentish fire." When the diastolic sound is doubled, the triple sound closely resembles the footsteps of a cantering horse heard at some distance, and to which Dr. Williams compared it.

This reduplication of the heart's sounds is seldom heard except in cases of disease, and, in the majority of instances, some abnormal sound is audible at the same time. Sometimes this phenomenon is only observed when the heart's action is quickened, and the sounds become regular as the action of the organ becomes tranquil. Some physiologists have endeavoured to account for this reduplication of the heart's sounds by supposing a want of synchronism between the movements of the right and left ventricles; but, from the manner in which the muscular fibres of the two ventricles are arranged, it is difficult to understand how their parietes could contract or dilate

alternately. An additional sound is sometimes produced by the apex of the heart impinging against the inferior edge of the fifth left rib during the systole of the ventricle, which, however, is not to be confounded with the phenomenon under consideration.

ADULTERATION OF COFFEE DETECTED BY THE MICROSCOPE.

At a recent meeting of the Botanical Society of London, a paper was read by Dr. Hassall "On the Adulteration of Coffee." By the employment of the microscope the author had ascertained that the substances most frequently used in the adulteration of coffee are chicory, roasted wheat, colouring matter, and occasionally beans and potato-flour. The structure of the coffee-berry, and of the several products just named, was then minutely described, and it was shown that the chicory might at all times be distinguished with the greatest ease by the size and ready separation of the cells, as well as by the presence of bundles of vessels of the dotted or spiral kind. The substance so generally employed to deepen the colour of coffee Dr. Hassall found to consist, in those instances in which he had examined it, of burnt sugar; and he referred to the fact that the rich brown hue of coffee is not peculiar to a decoction of that berry, but that almost all vegetable substances, when charred, yield a somewhat similar colour. The author then proceeded to detail, in a tabular form, the results of 34 examinations of coffee of all prices. From these it appeared that the whole of the coffees, with two exceptions, were adulterated; that chicory was present in 31 instances, roasted wheat in 12, colouring matter in 22, beans and potato-flour in one only; that in 10 cases the adulteration consisted of but a single article, in 12 of two, and in 10 of three substances; that in many instances the quantity of coffee present was very small, and in others not more than a fifth, fourth, third, half, and so on. Contrasting chicory and coffee, it was observed, that while the coffee-berry contains a quantity of essential oil, visible in small drops in the cells, and upon which the fragrance and the active properties mainly depend, not a trace of any similar oil is to be found in the chicory-root. It was advised that the coffee should be ground fine, in order to facilitate the liberation of the essential oil contained in the cells of the berry, and that an infusion, and not a decoction of it should be made.

Original Communications.

BRIEF NOTES ON THE DISEASE,
INDIAN VILLAGE CHOLERA,

AND ITS TREATMENT.

BY ASSISTANT-SURGEON MOORE, B.A.
Gwalior Contingent.

[Concluded from page 187.]

PART V.

Cholera a non-contagious disease: its origin.—The impression abroad is erroneous, that cholera is a visitation of recent date. Mankind, lay and professional, may rest assured that, from the hour the Almighty Creator of the universe breathed into man's nostrils the breath of life, the mucous membrane, and subjacent tissues of his stomach and intestinal canal, were as likely to be attacked with diffused inflammatory action as in this, the year of our Lord 1849-50. The public may rest assured that, so long as this world is peopled with human beings, or with a brute creation possessed of a stomach and an intestinal canal, their structures will continue to secrete serum, mucus, and lymph; and through their sieve-like tissues will percolate the saline ingredients of the blood. This, with its concomitant symptoms, is cholera: whether it occur in man or in beast, the results are nearly the same.

In the Israelitish camp, 1471 years before the commencement of the Christian era, cholera must have made its appearance. In the encampments of the tribes of Israel, thousands were swept away in the space of a few hours by a disease incorrectly translated the "plague." The term is incorrect, and has caused confusion. In the record of the miracles wrought by Moses, the Israelitish law-giver, in the presence of Pharaoh the king of Egypt, the term "plague" has been so far correctly used by the translators of the Old Testament, that at the present time the disease is recognised and described under the same name. There can be no difference of opinion as to the Egyptian "plague" of 1849 being precisely the same form of disease as the plague with which the land of Egypt was scourged in the reign

of Pharaoh. The description of the plague-proper, in the 19th chapter of Exodus, is accurate. The disease is described as "a boil breaking forth with blains upon man and upon beast, throughout all the land of Egypt." The translation of the second form of disease by the term "plague" is erroneous, because there is no form of epidemic which could have broken out suddenly in an encampment of the Israelites, which could have swept them away by thousands, and by tens of thousands, in the course of twenty-four or forty-eight hours, which could have disappeared entirely, or ceased as suddenly and unexpectedly, as it developed itself, save one,—that epidemic was, and is, cholera.

Divines, the ministers and interpreters of the religion of Christ, may not coincide in these views. Whether they assent or dissent, the question still remains one of opinion. It must be confessed, however, that the sudden and unaccountable cessation of the disease or plague in the camp of the Jews, after it had thinned their ranks, is strong presumptive evidence in favour of the identity of the Jewish epidemics in 1471 and 1472 B.C. and our annual epidemics in Indian villages, towns, cities, and cantonments. The sudden change from pestilence and death to a state of health, attributed to the exertions of Aaron, then, as now, may have originated in a shift of the Jewish camp,—in a change of wind,—a heavy fall of rain,—or in a thunder-storm, by which the pestilential state of the atmosphere was dispelled.

The passages in Holy Writ referring to the epidemic translated "the plague," may be found in—

Numbers, chap. xvi., v. 46, et seq.—
Year B.C. 1471; Deaths, 14,700.

46. "And Moses said unto Aaron, Take a censer, and put fire therein from off the altar, and put on incense, and go quickly into the congregation, and make atonement for them; for there is wrath gone out from the Lord: the plague is begun.

47. "And Aaron took as Moses commanded, and ran into the midst of the congregation; and, behold, the plague was begun among the people: and he put on incense, and made an atonement for the people.

48. "And he stood between the dead

and the living; and the plague was stayed.

49. "Now, they that died in the plague were fourteen thousand and seven hundred, beside them that died about the matter of Korah."

Numbers, chap. xxv., v. 8.—Year b.c. 1452; Deaths, 24,000.

8. "And he (Phinehas) went after the man of Israel into the tent, and thrust both them through,—the man of Israel and the woman, through the belly; so the plague was stayed from the children of Israel.

9. "And those that died in the plague were twenty and four thousand."

II. Kings, chap. xiv., v. 35.—Year b.c. 710; Deaths, 185,000.

35. "And it came to pass that night, that the angel of the Lord went out, and smote in the camp of the Assyrians an hundred and fourscore and five thousand: and when they arose, early in the morning, they were all dead corpses.

36. "So Sennacherib, king of Assyria, departed and went, and returned and dwelt at Nineveh."

In the year 1471, before the birth of Christ, Aaron is represented as standing between the living and the dead, and the plague was stayed. The expression is metaphorical. The description of the staying of the plague, in this written record, is oriental in its origin. Those who have witnessed, or have formed part of an Indian encampment, where 80 or 100,000 human beings have been congregated together, will at once perceive, that a separation between the living and the dead could be effected solely by the march of the living from the scene of death. In the march of the Israelitish camp, and consequent shift of ground, the pestilential locality and its victims—the dead corpses, in Scriptural language—were left in the rear.

There is nothing wonderful nor miraculous in an event of this nature. The instinct of self-preservation urged the Jews to a hasty march from an encamping ground, to have remained in which would have been certain death. The strongest, the stoutest, the healthiest, once seized with the epidemic, were smitten down in a few hours by an invisible death-stroke. The same occurs, yearly, in some one, part of the

Indian continent. In Lower Bengal I have resided within a few miles of villages where the cholera has broken out. When a fourth of the inhabitants had been swept away by its ravages, in the course of eight-and-forty hours, the remainder have rushed out in a body, with their wives, and children, and cattle. The villages have been deserted; a living soul did not remain behind in the ill-fated spot.

Time was allowed to elapse, until, in the opinion of their pundits, the wrath of the offended deities had been appeased, and the scourge had ceased. On their return to the villages they felt secure, and, as far as I could ascertain, seldom suffered from a fresh outburst of the cholera in an epidemic form. During their absence the state of the atmosphere, surcharged with noxious pestilential vapours, had undergone a change. Hence the cessation of the cholera, and the freedom from its attacks enjoyed by the villagers, after their return.

Holy writ does not stand in need of facts, such as the recorded epidemics in the Israelitish camp, so obvious and so easily explained, being distorted by the views of divines, and shrouded in the mysteries of miraculous agency. Holy writ does not need to exact from mankind an unconditional belief in the interposition and operation of miraculous agency, as to the origin, progress, and termination of a terrific epidemic scourge, when its sudden outburst and its sudden cessation can on reflection be accounted for in a manner perfectly rational, and consistent with the principles of religion.

The studied endeavours of writers to prove that cholera is a disease of recent development amongst the human race, have induced me to refer to the epidemics in the camp of the Israelites during their journeyings to the land of promise, as reasons for dissenting from their views. The fatal scourge or plague in the camp of the Jews must have been cholera, and no other form of disease.

This leads me to the non-contagious character of cholera.

The experience of the majority of writers and of observers, professional and non-professional, has established the fact that cholera is dependent upon, influenced by, and propagated through the medium of certain atmospheric

changes. Their observations prove that cholera does not spread by contagion, nor by infection—that is, the disease is not communicated from individual to individual by direct contact, but spreads and commits its ravages through the influence of the atmosphere.*

Others there are who entertain a different opinion. This class of theoretical contagionists is not numerous: their theories even are not well grounded: their views of the origin of cholera as an epidemic or as an endemic disease, are not comprehensive nor consistent: the facts upon which they ground their opinions, as to the contagious and infectious properties of cholera, tell equally in favour of the opinions against which they combat. In the list of contagionists figures conspicuously the name of Professor Graves, of Dublin. His reputation has been damaged by the obstinate tenacity with which he adheres to the erroneous views expressed as to the contagious and infectious properties of cholera in his published articles.

The matured opinion of practical

* After the second death from cholera the prisoners were removed from the jail into tents, and marched off to a short distance from cantonments. The jail was closed, whitewashed, and purified. The prisoners suffering at the time from the effects of cholera, or seized with the disease afterwards, were transferred to the Regimental Hospital. If cholera were infectious or contagious,—if a fretted and irritable, a crimsoned efflorescence, and sero-mucous eliminating condition of the mucous membrane from the stomach to the rectum were a disease communicable from one person to another, by contact or close vicinage,—the transfer, being fraught with danger to the sepoys in the hospital, would have been unjustifiable and censurable.

Contagionists would have drawn a quarantine boundary line round the hospital, and would have interdicted all intercourse with persons passing to and from the jail.

The hospital was crowded with patients. In the western verandah, when the centre ward and eastern verandah were full, several sipahis lay on charpoys between prisoners in the last stage of cholera. A single case of cholera did not occur among the sipahis who were in hospital at the time of the transfer. Nor did the disease exhibit itself in a single case admitted at any subsequent period with fevers, or ulcers, or contusions, or cutaneous eruptions. The case of Bahadar Sing, marked No. XLIII. in the Abstract, cannot be regarded as an exception.

The use of tartar emetic in the treatment of intermittent fevers was suspended for a short time, in consequence of vomiting and purging having supervened in a few cases. Tartar emetic, in its effects on the constitution, was more decided and more speedy in its operation than at any time previous to the outbreak of cholera. If such effects can be attributed to the transfer of the cholera patients from the jail to the regimental hospital, why be it so. The inconvenience was temporary, and was easily remedied.

observers in India has set the question at rest, that cholera,—the true type of the Indian village cholera,—originates in and travels from locality to locality, not through the medium of personal contact, but through the medium of an impure, a contaminated, an infected atmosphere: that such is the medium has been incontestably proved. The changes in the atmosphere satisfactorily account for the cessation, as well as for the prevalence of this form of disease during certain months of the year in India. They are sufficient to account for the outbreak of the same form of cholera in any other part of the globe besides India. Farther, the cause assigned for its outbreak, without reference to the theories of contagion and infection, accounts satisfactorily for the peculiarities and eccentricities of cholera, starting into existence in one region of the globe,—travelling from thence by forced marches,—becoming diffused over the earth's surface,—ravaging every country by turn, and sparing neither sex nor age in its progress.

With facts such as these in prominent relief before our eyes, we may reasonably inquire, of what value, of what practical utility, are quarantine laws?

Quarantine laws have already doomed to death healthy and unhealthy alike, crowded together in the close, ill-ventilated holds of vessels. In ignorance of the laws of disease, and through stupidity, when nations were panic-stricken, quarantine laws were framed as safeguards against the invasion of diseases regarded by executive governments as infectious and contagious, and exotic to the soil. With the sacrifice of human life on board of vessels undergoing quarantine, have these laws proved operative in protecting the inhabitants on shore from the outbreak of disease, erroneously supposed to be conveyed from one port to another in the hulls of trading vessels? Have the quarantine laws proved operative in shutting out from Great Britain, or from any port or state on the Continent of Europe, the malignant and erratic type of cholera, when the state of the atmosphere on shore was favourable to its development,—was favourable to its springing into existence without extraneous aid from the pestiferous holds of vessels afloat?

These are simple, straightforward

questions. Reply to them, if you can, advocates of the doctrines of cholera-contagion and of cholera-infection!

Past experience, sad and mournful though it be, has removed every doubt upon the subject, that quarantine laws have proved a gross delusion: they have proved ineffectual; totally inoperative as a safeguard against the invasion of cholera.

Quarantine laws, inoperative as a safeguard against the outbreak on shore of cholera, of typhus, of yellow fever, or of the plague, have inflicted the greatest miseries on the unfortunate passengers and crews, pent up in vessels, obliged to hoist the yellow flag. In the destruction of human life on board, quarantine laws have not proved inoperative.

Common sense has dictated, in the strongest and in the plainest terms, that when cholera or fever, the small-pox or the plague, have broken out on board-ship, the healthy and unhealthy should be separated without delay. Humanity—the laws of nature—point to the necessity of the speedy removal of the sick from the infected atmosphere on board to some healthy locality on shore. The experience of medical men practically acquainted with the essential character of the diseases for the exclusion of which quarantine laws are maintained in full force, has long since decided that, if the atmosphere on shore be infected, the detention of the healthy, the sick, and the dying, in the holds of vessels undergoing quarantine, cannot hasten nor retard the outbreak of epidemic diseases on shore. Experience has also set at rest that, if the atmosphere on shore be not infected—if the atmosphere on shore be not surcharged with noxious, pestilential vapours,—the removal of the sick and healthy from vessels afloat, as well as the discharge of their cargoes, cannot produce the changes in the atmosphere generative of those epidemic diseases against which quarantine laws have been framed.

That cholera owes its origin to, and starts into existence from, certain changes in the atmosphere, scarcely admits of a doubt. With the periodic changes in the seasons, and at those seasons of the year when strong and regular currents of wind do not sweep over the face of the land, cholera may rage as an epidemic or as an endemic disease. In this respect cholera is not

singular. At such time, when the purifying influence inherent in and exercised by strong currents of wind in dispersing accumulated exhalations from the soil is suspended, as well as when the atmosphere is surcharged with the devitalising principles of carbon, of sulphuretted hydrogen, and of other devitalising noxious vapours, generated in and exhaled from the soil, other types of acute inter-tropical diseases,—fever, dysentery, or the plague,—may ravage whole districts with greater destruction to human life than the worst type of cholera.

Cholera, when it rages on ship-board, is subject to the influence of the sea-breeze. Sea-faring, as well as medical men, can testify to the modified character of the disease at sea. In the effects produced by the fresh sea breeze, a transition takes place from sickness and mortality on board to a state of comparative health. I have already stated that this was the case on board the ship *Sophia*, when I proceeded to Mauritius in that vessel, in medical charge of coolies. A few solitary cases may occur in the interval of the three days' sail from the Sand Heads; but the symptoms do not present the same intensity of character, nor the same rapid tendency to a fatal termination, noticed in those attacked off Calcutta.

Another observation is worthy of record. During the prevalence of the south-west monsoon in the Bay of Bengal, cholera is known to disappear from a vessel much sooner than in the north-east monsoon. The south-west monsoon blows fresh up the bay: the north-east monsoon blows down the bay, from the river and land. Hence it is not unreasonable to infer, nor do we travel far beyond the limits of probabilities when we conjecture, that the breeze blowing from the land still retains, and is strongly impregnated with, the poisonous miasmata generated in and exhaled from the decomposed vegetable matter, and from the low swampy ground on either side of the river Hooghly at its entrance.

In mountainous districts, and in districts situated at the base of a hilly range, and lying to leeward of the range, through which strong and regular currents of wind cannot circulate freely, cholera may and has become the endemic scourge of the inhabitants. In towns and villages, and cantonments

In the plains, where a system of thorough drainage has been neglected, or a slovenly system of half measures in drainage is the rule and not the exception, the recurrence of cholera year by year may be looked for as a periodical visitation.

Within the tropics, the rapid and pestiferous exhalations from the soil, combined with certain properties inherent in particular descriptions of soil, appear to be intimately connected with that state of the atmosphere which predisposes to an attack of the mucous membranes, in preference to subjecting to its industries other structures in the body.

Examples illustrative of this marked predisposition to attack the mucous membranes may be found in the forms of disease by which the mortality amongst European troops, encamped in or marching through jungly districts, has been caused. In general, statistical returns furnish data from which no other conclusion can be arrived at than that the mortality among the troops has been caused by diseases directly or indirectly connected with the mucous membranes. The troops have been swept away by diseases which have broken out in the shape of cholera, of dysentery, of gastro-enteric fevers, or in that form of disease closely allied in its symptoms to the Egyptian plague. Inquiries as to the causes of mortality amongst natives living close to those pestilential spots, confirm the conclusions that the diseases prevalent among men, women, and children, are those connected with the mucous membranes.

Why this should be is difficult of explanation. The same difficulty exists in accounting satisfactorily for the development of inflammatory action in the fibro-serous membranes in preference to other structures, under an altered state of the atmosphere. This will be more distinctly understood by bringing forward a practical illustration.

The coolies who had been located on the sugar estates in Berbice and Demerara were embarked in the ship *Louisa Baillie* for the port of Calcutta, without being provided with a supply of warm clothing for the passage. Avarice on their part, and parsimony on the part of the agents of the estates from which they were shipped, left the coolies in a state bordering on nudity, to undergo all the vicissitudes of the weather, from

a calm to a hurricane. The Executive Government of British Guiana did not interfere, as the colonial Treasury could not be saddled with such an expensive item as the supply of clothing to Indian labourers, imported into the colony a few years before at the risk and for the benefit of private speculators.

Thus matters stood. Such is the gist of a subject which afterwards formed part of an inquiry by a parliamentary committee, in connection with the emigration of Indian coolies into the British West Indian Colonies. With the exception of bowel complaints, caused by the intermixture of verdigris with their food, sickness on board was slight, and the deaths from sickness few in number, until we reached the Cape of Good Hope.

The supply of water on board was running short. On the 25th of July, 1843, we sighted the Cape of Good Hope. On the 26th we entered False Bay in $18^{\circ} 45'$ east longitude, and $34^{\circ} 23' 48''$ south latitude. In beating up the bay, we narrowly escaped closing our voyage to Calcutta on the Anvil Rocks. They are invisible, sunken rocks,—a terror to mariners. A ripple, and then a breaker, warned us of our close approach to danger. The Anvil Rocks were close under our lee bow. In the evening we cast anchor opposite Simon's Town.

On the 2d of August, with a fresh supply of water in the ship's hold, but without extra clothing on the backs of the coolies, we weighed anchor, hoisted the sails, and beat out of False Bay in the night, against a strong south-easterly wind. With her head steering towards the southward, the *Louisa Baillie*, freighted with her living cargo of coolies, proceeded on her voyage to Calcutta. It is necessary to be particular as to dates. With each degree of southing made, from the 2d of August to the 27th of the same month, the intensity of the cold increased. During this time hail-storms were frequent; the weather was freezing cold, the decks were covered with sleet; whilst the vessel kept scudding before the wind under a close reefed main-topsail.

The sufferings of the coolies were severe in proportion. But the structures attacked and brought under the influence of disease were not the mucous membranes, nor the parenchymatous tissues: they were the fibro-serous

membranes of the joints, and of the cavities of the abdomen; the chest, and the head. In two cases, which terminated fatally in the course of fifteen hours, the peritoneum, the pericardium, and the pleura, exhibited, in the post-mortem examination, a degree of intense vascularity. Their smooth and polished surfaces were coated with soft semi-gelatinous lymph recently exuded; their cavities contained serous fluid tinged with the red particles of the blood: flakes of lymph floated about in this serous fluid. The mucous membranes were healthy. The solid viscera were free from inflammatory action, with the exception of their fibro-serous envelopes. Whether the cases recovered, or whether they terminated fatally, the force of the disease was directed towards, and seemed to concentrate in, the fibro-serous membranes. Nor did any obvious change take place in the structures attacked until we crossed the line, in longitude 83° East, on the 18th of September, 1843.

There is no difficulty in assigning the reasons for the sufferings of the coolies from the intensity of the cold. They needed warm clothing. The difficulty consists in assigning reasons for the fibro-serous membranes of all other structures in the body having been selected as the seat of acute inflammatory action.

The question remains to be solved, in like manner, why the mucous membranes should be selected for attack, and be subject to specific morbid changes, when the surrounding atmosphere is surcharged with noxious pestilential vapours. It must be confessed that in this respect our knowledge is limited.

In India, medical men are aware that the prevalence of a particular form of disease in a locality can in general be traced to the nature of the surrounding soil. Medical men are aware that in jungly uncultivated districts, in localities where black and loamy soil, or a virgin soil topped with successive layers of decomposed vegetable matter, abound, health may be regarded as the exception, disease the rule. Through this description of soil, black, loamy, and impervious to water, rain does not rapidly filtrate. So long as the moisture of the ground is kept up to the point of thorough saturation, exhalations injurious to health do not appear to be generated.

But, when a heavy fall of rain has been followed by a long-continued drought, the "avant-courier," the forerunner of an epidemic scourge, impure, noxious, and devitalising exhalations are emitted by day and by night, in consequence of the powerful heat of the sun acting on a soil in the body of which so much moisture has been retained. In selecting sites for cantonments, or ground for encampments, military surgeons are aware that such localities ought to be avoided.

Again, in India, the sources from whence the cholera-producing changes proceed are numerous. Numbers of the medical profession, who have interested themselves in ascertaining the actual condition of the poverty-stricken in this country, by strolling through Indian villages, and viewing, for their immediate information, the heaps of nuisances which meet the eye at every corner, can be at no loss to account for the prevalence of disease, and for the mortality which follows in the wake of disease in every village in India.

So far as heaps of manure; so far as cesspools, half filled with stagnant water, and half filled with rotten vegetable garbage; so far as huts, closely crowded together, ill-ventilated, built on swampy undrained soil; so far as the wretched condition of the mass of the people, removed but one degree from actual starvation; so far as the carrion, half devoured by the village scavengers, swine, and pariah dogs, kites, and vultures, can contribute to the production and propagation of disease, in Indian towns and villages, through the medium of a foul, infected, pestiferous, and poisoned atmosphere:—such they fail not to do.

To propose a remedy for these evils would be equivalent to effecting a thorough reformation in the sanitary condition of India. The cleansing of the Augean stables, a work of Herculean labour, would dwindle into insignificance, compared with the cleansing of Indian villages in a single district.

Of all this we possess the strongest proofs: yet we are forced to return to the point from whence we started, without being able to assign a convincing reason for acute inflammatory action being devitalising, in memt

influence of an altered state of the atmosphere.

The admixture of noxious, devitalising vapours with the blood, through the pulmonary tissue by inhalation, and through the cutaneous surface by absorption, whether generated in the earth, or emitted from any other source, approximates so closely to a rational explanation for the outbreak of an epidemic scourge in a particular locality on shore, or in the hold of a vessel afloat, as need be assigned. For practical purposes more is not needed. The subsequent attraction or determination of the vital fluid thus impregnated to the capillaries and surface of the mucous membranes in one instance,—to the capillaries and surface of the fibrous membranes in another instance, may be left to speculative theory and theorists, in so far as mankind will derive any benefit from the discovery.

A CASE OF TWO CALCULI IN THE BLADDER:

ONE REMOVED BY THE OPERATION OF
LITHOTRITY, WHILE THE OTHER RE-
MAINED IMBEDDED.

BY JOHN GRANTHAM, F.R.C.S.E.

I was sent for on the 7th of April, 1847, to visit Mr. A., a farmer, aged 57 years, whom I found suffering very severely from all the symptoms of calculus in the bladder. The urine gave the following analysis: specific gravity (average) between the *urina sanguinis* and the *urina cibi* 1.007, colour pale straw, semi-transparent, acidity normal, urates in excess, with a few triple phosphates, albumen, blood corpuscles, and epithelial scales, denoting what my late esteemed and valued friend Dr. Prout would call "serous urine."

April 8th.—I introduced a sound into the bladder, and struck a calculus. On carefully exploring the stone, I came to the conclusion that it was of such a size as to justify its removal by the operation of lithotripsy, which operation I performed on the 14th of April, 1847. On securing the stone within the blades of the instrument, I ascertained the fact that the calculus measured $\frac{3}{4}$ ths of an inch in one diameter. On the seventh day from the first operation I again examined the

bladder, and broke up the remaining portions of stone: the whole of the fragments passed per urethram. I make this latter statement with great confidence, as this fact will be proved in a subsequent part of this paper. For the space of nine months the patient enjoyed the benefit of the operation with total absence of all the symptoms of calculus in the bladder. After the above period, owing to undue exposure to damp, &c. he received a chill, which was followed by an immense discharge of mucus from the bladder. On examination I found the prostate very large,—at least such was my evidence both by the urethra and the rectum. This attack was succeeded by others, with an interval of two or three months, each becoming more and more severe. During the last five months I considered the bladder quite empty, but thickened in its structure; yet this idea was at variance with the symptoms, from the patient's inability to retain any quantity of water in the bladder: and this circumstance reminds me of the difficulty, during the operation of getting the bladder to retain even one syringe-full of water, and that amount passed out in considerable quantity by the side of the instrument whilst endeavouring to grasp the stone.

June 17th, 1850, Mr. A. died; and on the following day I made a post-mortem examination, when the subjoined facts presented themselves:—Both kidneys were in a state of eccentric hypertrophy, with a granular soft appearance of the cortical portion, which was also studded with tubercular deposits; the pelvis and lining membrane of both kidneys being in a state of extensive ulceration, one ulcer in the *left* kidney nearly through its cortical substance. The bladder presented a corrugated appearance externally; the coats were thickened, but very soft; and, on taking off the fundus, I found a large calculus weighing five ounces and a half, imbedded in the folds of the lining membrane, extending to the under portion of the prostate gland, and not a single fragment could be found besides in the bladder. This immense stone, be it observed, was so firmly imbedded as to require much force for its removal: the upper surface was denuded of mucous membrane, which, I infer, could only have become so during the last five months.

Inferences drawn from the above statement:—

1. The great length of time required to produce so much disease.

2. That the disease of the kidneys preceded that of the calculous formation, as without doubt *both* calculi were formed in the pelvis of the kidney, both ureters being very large in diameter.

3. The complete removal of the first stone by the operation of lithotripsy, and the further establishment of the proposition that a fragment does not form the nucleus of a second stone.

4. The impossibility of saving the life of the patient, by the performance of the operation of either lithotripsy or lithotomy.

In conclusion, this case forms an example of the effects of over-looking, or not having had the opportunity of observing, the early symptoms; and I would remark that those symptoms or causes could not have been discovered by the practitioner unless he had taken

the trouble, and truly possessed the knowledge, of examining, both chemically and microscopically, the secretion of urine at the outset, when the disease might have been arrested. Censure, however, ill becomes any one of us, knowing how liable even the most experienced are to err in their judgment.

Chemical Examination of the Calculus.

By ALFRED S. TAYLOR, M.D., F.R.S.
Lecturer on Chemistry in Guy's Hospital.

The calculus was of an oblong, ovoid form, rather flattened, and wider at one end than the other. The exterior was of a whitish-brown colour, crumbling and soft, with a few irregular shallow depressions, but there was no sharp angle in any part. It measured about three inches in length, two and a half inches in the wider and one inch and a half in the narrower portion.

Outline of form and size.

b b, line of section.

Externally it was dry, but internally soft when cut. Its weight was 1920 grains, (about four ounces.)

When sawn through, it presented an irregular oval section, the irregularity being caused by the super-position of a

whitish deposit, of a somewhat conical form, on the flat surface of the oval. The greater diameter of the oval measured $2\frac{3}{4}$ inches, the shorter diameter $1\frac{1}{4}$ inch, and the adventitious deposit (a) half an inch.

The nucleus was of a dark-brown colour, and situated about the centre of the oval. It presented a flattened oval in section, about one inch in length, and half an inch in width. The nucleus presented a somewhat cellular and not a regularly lamellated structure, except at the circumference. With the exception of the nucleus, the whole section of the calculus presented a chalky-white appearance. There was a very regular deposit of laminae immediately around the nucleus, but these became irregular

towards the circumference, especially at the upper part.

By the usual chemical processes it was ascertained that—

1. The *nucleus* consisted of lithic acid, with lithate of ammonia.

2. The *body*, of phosphate of lime alternating with layers of lithate of ammonia.

3. The *crust*, or external portion, of phosphate of lime, with phosphate of ammonia and magnesia.

Chemical Laboratory, Guy's Hospital,
June 25th, 1850.

ON THE ORIGIN, CAUSE, AND NATURE OF CHRONIC OVARIAN TUMORS.

By EDWARD JOHN TILT, M.D.

Physician to the Farringdon General Dispensary,
and to the Paddington Free Dispensary for the
Diseases of Women and Children.

WE have fully detailed in another periodical* all the varieties of the morbid cystic structure to which the ovary is liable, before venturing on any inquiry respecting their origin, or before we attempted to grasp (as far as it is permitted) the chain of their causation and the knowledge of their nature. If we begin by directing our attention to those closed cavities, natural or accidental, which are so numerously developed in the organization, we see that they have been wonderfully ordained to isolate the organs they surround, and to permit their independent action. Has not an important object been attained, by clothing these natural cavities with a serous membrane, lubricated by fluids? The accidental cavities developed in the frame are not less important. Our cor-

poral structure is liable to be invaded by so many and various bodies, that it was thus necessary to provide for the emergency, in order that whatever might be wrongfully introduced into our substance, should, if possible, be assimilated, or, failing this, at least be isolated, until it could be ejected.

That cellular tissue, which resembles serous membranes in its functions as well as in its structure, which separates the organs one from another, and binds them together in one harmonious whole, has, in each of its multitudinous cells, the power of secreting and absorbing the serum by which they are filled.* If, therefore, a ball or any foreign substance be forced into the body, the cellular tissue of the part where it is deposited forms around it an adventitious serous cavity, secreting a serous fluid; and thus the foreign body may remain

* Although the liquids effused in the areolar tissue are, like the blood in our veins, under the influence of gravitation, we cannot admit that these fluids are effused in the areolae of this tissue by mere physical transudation. This explanation can no more account for the presence of serum in the areolar tissue, than it would for the large cysts accidentally developed in the same tissue.

* *Lancet*, 1850.

for years isolated, and therefore harmless. In a similar manner, if, from any given cause (and there are many), blood be forced from those channels wherein it was destined to run its continuous course into the substance of the brain, lungs, or any other of our tissues, that ubiquitous cellular tissue receives it, and from itself forms a serous membrane to surround it on all sides; and as the substance thus inclosed is homologous to the inclosing body, it is sometimes completely absorbed, and the accidental cavity diminishes and disappears. Sometimes, however, the cavity remains, secreting and absorbing like any natural serous cavity; and when found by the anatomist it no longer reveals to him the origin and cause of its existence—the blood clot. In other cases this blood clot is only partially absorbed, and thus reveals the origin of the cyst, by its colour and appearance. We may therefore infer that wherever cellular tissue exists, there an hematic cyst may be developed. From the uncontested properties of the cellular tissue, we may also derive the origin of many other accidental cysts, so frequently met with; for every individual areola of this tissue secretes and absorbs; and, as it holds communion with the neighbouring cells, we find them all alike distended in oedema and anasarca. But certain areolæ are sometimes cut off by inflammation, or some other cause; and thus arises a serous cavity, the increase of which will depend on the nature of the organ wherein it is formed, as well as on a variety of other causes: cysts of the eyelids and of the mammae, the synovial bursæ of the patella, the ganglia, or tumors formed on the sheaths of tendons, may be thus satisfactorily explained.

We have thus deduced two origins for accidental cysts, as depending—1. On the nature of the areolar tissue, which permits one or more of its cells to set up on its own account; 2. On an hematic origin. We may also add, that whereas there is a great uniformity in the liquid produce of natural serous cavities, the serum being transparent, light-coloured, and of a low specific gravity, there is also uniformity in the nature of the fluid contents of all accidental serous cavities, the liquid being more complex in its nature, of a more considerable density, and often mixed with fatty substances and cholesterine. Applying to the subject under consideration these deduc-

tions from the laws of general pathology, we shall have at least the origins of ovarian cysts; for cellular tissue enters into the structure of the ovary, and blood may also be extravasated into its tissue: and admitting, with De Graaf, and with Langer, that, besides the Graafian follicles there are minute vesicles in the stroma of the ovary,—a fact lately confirmed by the microscopic researches of Heale,—we may believe that they are sometimes the seat of intra-ovarian fibro-serous cysts; while the extra-ovarian, which are always fibro-serous, and those formed in the broad ligaments, can only be thus explained. Dupuytren, Chaussier, and others, believed that all ovarian cysts were adventitious; but a slight inquiry into the nature of the ovaries will soon convince us that these are not the only original seats of ovarian cysts, and that we may believe, with Cruveilhier, Pr. Stoltz, and many other writers, that they often originate in the Graafian follicles. The ovaries are cellular in their structure; and it was necessary that they should be so, to render them fit receptacles for the human germ. Every month, during the productive period of a woman's life, is marked by the enlargement of a follicle, which may or may not burst. If it burst, the remaining cavity will be filled with blood, which may, or may not, have been absorbed when a succeeding menstrual effort comes to give increased energy to any healthy or morbid action in which the ovary may be engaged. We have, therefore, in the cystic structure of the ovary, and in the monthly fertility of its soil, additional reasons for the frequency of ovarian cysts; and the possibility of uncontrolled distension, which, from their situation, they necessarily enjoy, is a reason for their increased hydatids.

Very little is known of the origin and causes of hydatid formation in general, and, in particular, of hydatid ovarian cysts. These bodies are formed in fibro-serous cysts; and although the cause of their production is unknown, they may very likely depend upon some unhealthy condition of the blood; but still we know not in what that condition may consist. Thus it has been observed that, in almost every instance of hydatids, the general health has been, for a long time previous, considerably deranged: and it appears that Dr. Jenner produced hydatids and fluke-worms in rabbits, by

feeding them exclusively on succulent food. These experiments acquire additional importance since the publication of Dr. Schleisner's account of the diseases peculiar to Iceland: its corn, esculent roots, and fruit, will not grow in that island; the inhabitants eat little bread, or vegetables, and live upon dried fish, dried meat, butter, tallow, train oil, and blubber. The probable result of this exclusively animal diet is a frequency of hydatid growths unknown in any other country. Hydatids formed one-eighth of the cases enumerated, and one-sixth part of those observed by Dr. Schleisner, who remarks that in one parish he met with two or three sufferers from this disease in every family.—(Review of Dr. Schleisner's book, British and For. Med. Ch. Review, January, 1860.)

Unassisted by an imposing array of facts to account for the origin of these productions, we must have recourse to analogy, and to what we have learned from comparative physiology respecting the generation of our tissues. In explanation of these laws, can we do better than borrow from an illustrious countryman, who has already raised himself a name which must descend to posterity, Professor Owen? who, in his valuable lectures on generation, lately delivered at the Royal College of Surgeons, says,—“The primitive forms of all tissues are free cells, which grow by imbibition, and which develop their like from their nucleus of hyaline. All the animal tissues result from transformations of these cells. It is to such cells that the acephalocyst bears the closest analogies in physical, chemical, and vital properties. When the Infusorial Monads are compared to such cells, and man's frame is said, by a figure of speech to be made up of such monads, the analogy is overstrained, because no mere organic cell has its mouth, its stomach, its pulsatile sac, &c. So also it appears to me that the analogy has been equally overstrained, which makes the acephalocyst a kind of monad, or analogous species of animal. We may, with some truth, say that the human body is primarily composed or built up of acephalocysts; microscopical, indeed, and which, under natural and healthy conditions, are metamorphosed into cartilage, bone, nerve, muscular fibre, &c. When, instead of such change, the organic cells

grow to dimensions which make them recognizable to the naked eye, such development of acephalocysts, as they are then called, is commonly connected in the human subject with an enfeeblement of the controlling plastic force, which, at some of the weaker points of the frame, seems unable to direct the metamorphosis of the primitive cells along the right road to the tissues they were destined to form, but permits them to retain, as it were, their embryo condition, and to grow by the imbibition of the surrounding fluid, and thus become the means of injuriously affecting or destroying the tissues which they should have supported and repaired. I regard the different *Acephalocysts*, therefore, as merely so many forms or species of morbid or dropsical cells.

“The question which remains to be solved is, how the parent hydatid originates; two modes may be conjectured: either it is the result of the development of an organic granule, nucleus, or cell, of the animal infested, according to the hypothesis of fortuitous or spontaneous generation; or it is developed from an impregnated germ-cell detached from a pre-existing acephalocyst, and potentially endowed with the special mode and direction of the plastic force which issues in the repetition of the same organic form as the animal from which it proceeded. Analogy points to the latter as most accordant with actual physiological experience.”

Whatever may be the cause of these singular bodies, when once originated they may for years continue to reproduce similar bodies. The late Dr. Ryan has recorded a case in which hydatids were retained in utero so long as 14 years.

Piliferous cysts.—In some rare instances the impregnated germ falls not into the fallopian infundibulum, but remaining attached to the ovarian birth cell, gradually appropriates to itself the tissue of the ovary, and so distends it as often to attain a considerable size. These fetal cysts may remain stationary for years. Sometimes the fœtus is reduced to a kind of mummy, but at others it undergoes decomposition, the soft parts being converted into various kinds of fatty matter. While portions of skin of the fœtus become attached to the interior of the cyst, reproducing by its bulbs the hair which is so often found in considerable quan-

titles, the more solid parts, such as the bones and teeth, remain to indicate the origin of the cyst.

We are thus led to infer, that piliferous cysts are sometimes only fetal cysts, wherein the greater part of the body has undergone decay. But does this explanation hold good in all cases of piliferous cysts? M. Pigné, who has paid great attention to this subject, does not hesitate to assert that all piliferous cysts are either the result of extra-uterine pregnancy, or of a malformation; that, for instance, when piliferous cysts are found in girls of a tender age, or in young boys, we must believe them to be relics of some other individual contemporary with the one in whose body they are implanted; and that it was in an early stage of their existence that somehow or other one of the two became included in the other. Those who must have an explanation of the fact, and who can never, as Montaigne so quaintly says, "make up their minds to lay quietly their heads on the pillow of doubt," may admit this explanation, but it is surely better to confess our ignorance than to attempt to explain the inexplicable. If we had merely to account for those piliferous cysts growing in the vicinity of the shin, in the scalp, the eyelid, the mamma, and the scrotum, we might, as Carswell suggests, consider the hair they contain as arising from accidental development, as it grows from the anterior portion of these cysts which is lined by the reflected cutaneous tissue; but such an explanation could not account for the hair and teeth found in the ovaries of virgins, in the coats of the stomach and of the bladder of man, in bronchocele as mentioned by Celsus, in the abdomen of a boy by Dupuytren and Mr. G. W. Young, in the lungs by Möhr, in the brain by Morgagni, and in the orbit by Barnes. (Med. Chir. Trans. vol. iv.)

Without pretending to explain the fact, we must observe that in all well-authenticated cases the interior of the cyst has been found to be lined with a substance like the skin, with bulbs producing hair. Cruveilhier, Velpeau, Carswell, and many others, have seen cysts partially lined with skin; in a case recorded by Bricheateau, the cyst was entirely so lined, and this must also have been the case in the instance quoted by Morgagni, from the author of an opusculé, (*de Ovarii tumore pilosâ,*)

Liepsick, 1786), who does not scruple to compare the cavity of the cyst to the scalp. It must be a tissue similar to skin, for it not only secretes fat and sebaceous matter, but hair has been repeatedly seen to grow from its bulbs, horny productions have been known to spring from it, dental sacs and teeth have been found rooted in it: and these are all epidermoid productions. How a fragment of skin could thus be found we cannot explain, but it seems as if the vegetative life adherent to each of the germ-cells which constitute our frame, were able sometimes to produce the "horn layer," (mucous layer), or that portion of the germinal layer which covers the embryo, and is the foundation of the non-vascular and nervous tegumentary appendages. Here, again, we willingly quote from Professor Owen's second lecture on the generation and development of invertebrated animals, in order to bring the light of comparative physiology to bear on the more abstruse points of pathology.

In many classes of the invertebrate animals the retained spermatic force operates with such energy as to form a new individual from a secondary, tertiary, or quaternary derivative germ mass. How this is done we know not; suffice it to say that it is done. The completion of an embryonic or lowest form by the development of an ovarian germ-cell, as in the aphidæ, without the immediate reception of fresh spermatic force, has never been known to occur in any vertebrate animal; in the vertebrate animal, the whole of the spermatic force, originally diffused amongst the cells or nuclei of the germ mass, is exhausted in the development of the tissues and organs of the individual, in the mysterious renovation of the spermatic power in the male, by a special organ; and in the development of ova or cells prepared for its reception in the female. But it now and then happens, even in the highest of the vertebrata—the human species—that the ovarian cell sets up the process of embryonic development, but without sufficient of the spermatic and plerotic power to complete even a lowest form: some crude materials of the embryo are the only result,—teeth, it may be, or hair, with irregular amorphous ossifications, such as are met with occasionally in ovarian cysts.

Whatever may be the origin of such epidermoid appendages, they are more frequently found in the ovary than in any other organ, and Meckel asserts that they are more frequently found on the right side. They are met with at all ages: in 49 cases collected by M. Pigne, 5 were not 12 years old, the age of 6 varied from 6 months to 2 years, 4 were full-grown fetuses, and piliferous cysts were also found in the ovaries of 2 fetuses which had been cast off before the end of the ninth month.

These cysts may communicate with the bladder, as in the case given by Suetin, (An. de Med. Belge, 1838), where a tooth was found forming the nucleus of a stone in the bladder. Hair has likewise been passed in the urine by a communication between the bladder and a piliferous cyst, but Magendie has published cases of gravel, wherein hairs were passed mingled with the usual saline conditions. Where did these hairs come from? Were they secreted by the kidneys?

It is well to know that such productions are not peculiar to the human species, and that the hair of the cow and the wool of the sheep have been found in the ovaries of these animals.

Penada found a fatty bag containing two bunches of feathers, 33 in number, in the breast of a young cock.

6, York Street, Portman Square.

FATAL CONGESTION OF THE BRAIN,

OCCURRING IN AN INFANT WHILE TAKING
COD-LIVER OIL.

By W. B. KESTIVEN, Esq. M.R.C.S.

THE death now recorded is not related as being the undoubted effects of cod-liver oil: it is put on record as worthy to be known, whilst the properties of this oil are undergoing an extensive examination by the profession. It is meant as a contribution to that examination, and may serve to teach caution in the use of cod-liver oil. At the same time the writer distinctly avoids the application of the *post ergo propter* line of argument in this case.

H. O—, aged one year and nine months, was attacked on the 17th June with symptoms of congestion of the brain, which were attributed by me to dentition. The means employed were

attended with success, and the child was quite well on the 24th of June. On the 27th the child was again seized with more grave symptoms of cerebral congestion: it was convulsed, its head was hot, its bowels disturbed, and it had frequent vomiting of bile. Treatment, this time, was of no avail. The child died in the course of two days. A post-mortem examination was refused.

The history of the case here follows. This child had been, according to its parents' account, a "delicate child" from its birth. About fourteen months since I was consulted with reference to a curvature of the spine which it presented in the dorsal region;—the result of bad nursing. Strict adherence to the horizontal posture, nourishing diet, and plenty of fresh air, were advised. The child's health improved, and the back had very much improved. Some kind friend, who could not let well alone, urged the parents to give cod-liver oil. This was done, and its use in full doses continued for several months previously to the first attack of cerebral congestion. The parents had asked my opinion of the oil (after having given it for some time). I did not advise its discontinuance, partly for the sake of not seeming to be captious, and partly because I looked upon it only as so much food, of which I hoped it might not get too much. Its use was discontinued while under my care for the head symptoms; but, directly health was restored, so also was the cod-liver oil (by the parents). The rest of the case has been told above.

It may be repeated, that the child's death is not positively attributed to the cod-liver oil; but the writer thinks it highly probable, that if it had not been administered—at least, to the extent, and at the time that it was—the child might not have died of congestion of the brain.

Holloway, July 1860.

SLOUGHING ULCERS.

No case of fatal hospital gangrene has occurred in the Pennsylvania Hospital wards during the last four years or more. The disease, as an epidemic or endemic, is unknown there. Where a sloughing tendency was perceived, the applications which appeared to the writer of most service, were the carrot poultice, and the wash of nitric acid, used daily, *gtt. 1.* in Oj.—Dr. Hartshorne, in *American Journal of Med. Sciences*, 1850.

MEDICAL GAZETTE.

FRIDAY, AUGUST 9, 1850.

In reference to the remarks made in a recent number* on the enforcement of privileges by English and Scotch Corporations, it has been suggested to us by an Edinburgh physician, on whose opinion we are inclined to place great reliance, that the charge of illiberality cannot be fairly made against the Scotch Colleges. The writer informs us that English members and licentiates are not persecuted in Scotland. The Edinburgh College of Surgeons, with ample privileges, has not prosecuted any one for practising within its bounds for half a century; and on that occasion the prosecution was directed against a person who held no license whatever—a mere quack: therefore, so far as the liberty of practising in Scotland is concerned, the charge is unfounded.

The Colleges of Surgeons of Edinburgh and London pursue, however, a widely different course with respect to the members and licentiates of each. The English College of Surgeons has the following among its regulations:—

“II.—Members or Licentiates of any legally constituted *College of Surgeons* in the United Kingdom, and Graduates in Surgery of any University requiring residence to obtain degrees, *will be admitted for examination* on producing their *diploma*, license, or degree, together with proof of being twenty-one years of age, and of having been occupied at least four years in the acquirement of professional knowledge.”

There is here no inquiry into the minutiae of curricula or courses of education,—a subject upon which no two licensing corporations ever have agreed,

never will agree,—but a free and liberal recognition of the right of the Scotch member to examination. The practice of the Scotch College is set forth in the letter which led to our remarks.* The writer says—

“I applied to the College of Surgeons of Edinburgh to admit me to examination on producing my diploma of the College of Surgeons of England. I was refused to be admitted to examination unless I possessed certificates of lectures on all the classes required by the Edinburgh College. Surely this is hardly an act of courtesy, when the London College admits licentiates of the Scotch College to examination solely on production of the Scotch license.”

We believe this statement to be strictly correct; and so long as this system is adopted by the Edinburgh College, it must create great dissatisfaction among members of the English College. A comparison of curricula is assuredly not needed, when the course of study and examination enforced by the London Colleges qualifies a man to practise as a surgeon throughout England and Wales, and makes him eligible to hold any surgical appointment in the kingdom. By rejecting the English diploma as a sufficient testimonial for admission to examination, the Scotch College passes a severe censure upon the English College of Surgeons, and upon all who are connected with it. One great step to an amalgamation of practice in the United Kingdom, would consist in the different corporations recognising their respective curricula in medicine and surgery as sufficient at least for the purposes of *examination*: and on this point we regret that the English College should have adhered so strictly to the *letter* of its regulations as to refuse examination to a licentiate of the Glasgow Faculty of Physicians and Sur-

* See our number for July 12th, p. 67.

* See MEDICAL GAZETTE, July 12, p. 67.

geons.* We presume, however, as the Glasgow license is for physic as well as surgery, there was some legal difficulty in the way of making the concession in this instance.

The curriculum of the English College has produced, and still produces, many excellent surgeons: and there is nothing to justify that distrust of the extent of study, which is shown by the Scotch College in refusing to admit to their examination those who possess its diploma.

THE necessity for some legislative measure to prevent the frequent destruction of life which occurs by explosions in coal-mines, has been long apparent. A catastrophe of this kind, in which from fifty to one hundred persons lose their lives, occasionally leads to inquiry, but unfortunately no practical measure to arrest these calamities is based on the successive inquiries. An accident has only recently occurred at Glasgow, in which nineteen persons out of twenty lost their lives by the explosion of fire-damp in a coal-mine. In general all are destroyed, and the cause of the accident becomes a matter of pure speculation. In this instance, one person escaped, and we learn from his statement that "the men had not Davy lamps." We believe that these calamitous explosions are generally due to the want of the lamps or to the improper use of them; and if the Government desire to arrest the wholesale destruction of life, the simple remedy will be to appoint inspectors of Mines, who shall be empowered to see that the men are provided with properly constructed and well-secured lamps. A short Act of Parliament would, we believe, suffice for securing the miners, while it would not injure the rights of proprietors.

* See our number for July 26th, page 170.

THERE appears to be a considerable difference of opinion regarding the nature of the questions which can be legally put to medical witnesses in civil and criminal cases affecting the insane. On the occasion of the trial and acquittal of M'Naughten for shooting Mr. Drummond in the year 1843, a series of questions was submitted to the judges by the House of Lords; and one of these (Question V.) bears directly upon the limitations to be put on medical opinions regarding the insanity of individuals. The question was as follows:

Question V.—Can a medical man, conversant with the disease of insanity, who never saw the prisoner previously to the trial, but who was present during the whole trial and the examination of all the witnesses, be asked his *opinion as to the state of the prisoner's mind*, at the time of the commission of the alleged crime; or his opinion whether the prisoner was conscious at the time of doing the act, that he was acting contrary to law, or whether he was labouring under any, and what delusion at the time?

Answer. The question could not be put in the precise form stated above, for by doing so it would be assumed that the facts had been proved. When the facts (indicative of insanity?) were proved and admitted, then the question, as one of science, would be generally put to a witness under the circumstances stated in the interrogatory. [Mr. Justice Maule dissented from his learned brethren. In his opinion such question might be at once put to medical men without reference to the facts proved.]

The right of putting such a question to a medical witness was, however, recently denied by Mr. Baron Alderson, in a trial which took place at the Old Bailey; but, instead of preventing the question from being put, the judge, on this occasion, rebuked the witness for returning an

answer! The question again arose in an important will-cause—*BAINBRIDGE versus BAINBRIDGE*—lately tried at the Stafford Assizes, before Lord Campbell, in which it was alleged that the testator was insane, and that the will which had given rise to the suit was therefore invalid.

A large mass of evidence was adduced, to show that the testator was not conscious when the will was executed; and that for some time previously, his habits and conduct were such as could only be explained on the supposition that he was insane. We are then informed that

towards the conclusion of the plaintiff's case, Dr. Monro, Dr. Conolly, and Dr. Forbes Winslow, were put into the witness-box to give evidence on the question of insanity, and were allowed to give general scientific evidence on the causes and symptoms of insanity, but *not to express an opinion as to the result of the evidence they had heard with reference to the sanity or insanity of the testator*, his Lordship saying peremptorily that he would not allow a physician to be substituted for the jury. The Solicitor-General hereupon proposed, in form, the following question to the first witness, Dr. Monro, for the purpose, if it should be necessary, of having its propriety determined in the court above: *'Having heard the evidence in this case, are you of opinion that this gentleman was or was not of sound mind?'*

Mr. KEATING objected to the question.

LORD CAMPBELL.—I have not the smallest hesitation in overruling it.

His Lordship, at Mr. Cockburn's request, took a note of the point.

Dr. Monro was subsequently proceeding to state, in answer to a general hypothetical question from the defendant's counsel, an opinion upon the facts proved in the cause, when

LORD CAMPBELL interposed, and *peremptorily requested him not to express any opinion on those facts, but to confine himself to general scientific principles.*

We are at a loss to reconcile the proceeding of Lord Campbell with the answer of the fifteen judges. The "facts," on which the plaintiff relied to make out evidence of insanity, were "proved

and admitted:" and we do not see the any injustice would have been caused to the case of the defendant by allowing the three medical witnesses to express an opinion on these facts. The jury might or might not have been guided by that opinion, which, it may be remarked, could only have had force in proportion as it was in accordance with the evidence, and with common sense.

The peremptory direction of the judge, that they should confine themselves to *general scientific principles*, is tantamount to affirming that medical evidence is of no value in such cases. In a case of death alleged to have been caused by a blow on the head, it would be considered rather an eccentric ruling on the part of a judge, that a medical man should not be permitted to express an opinion of the cause of death, from the "facts" that the deceased had fallen dead after having sustained a severe blow, which had fractured the skull and ruptured the lateral sinus. The ruling in the Stafford case, if correct, would, however, lead to this:—a medical man so situated, would not be permitted to express an opinion on those "facts," or to say, in answer to a question, that death was caused by the blow proved to have been inflicted by the prisoner; for this would be substituting him for the jury. The witness would have to confine himself to "general scientific principles,"—i. e. to blows on the skull in general, and to the effects of a lacerated lateral sinus in the abstract.

If a physician affirm that a person is insane when the facts fail to bear out the opinion, the jury correct this error by refusing to act upon his judgment, just as in the assumed case of manslaughter they would not be guided by the opinion of the surgeon, unless it were borne out by the circumstances proved. We are at a loss, therefore, to know why this peremptory direction to

keep to anything medical, except that which had immediate reference to the case under trial, should have been laid down as the law by Lord Campbell, when it is in open violation of the answer returned by the judges on this very point.

We must admit, however, that the answer somewhat resembles the responses of the Delphic oracle: it may be read in two or three different ways. We here take it in its plain meaning: certain facts are proved and admitted. Do those facts lead to the conclusion that the person affected by them is insane? The fifteen judges say this is a question which may be fairly put to a medical witness. Mr. Baron Alderson and Lord Campbell hold that a question of this kind is for the jury only, and not for a medical witness: but, unless the jury be well versed in the subject of insanity, their verdict will, in many cases, be only a random conjecture.

NEW METHOD OF RELIEVING RETENTION OF URINE WITHOUT THE USE OF THE CATHETER. BY M. J. J. CAZENAVE.

WHEN called to a patient having retention, complete or incomplete, M. Cazenave in the first place directs the large intestines to be cleared out by an enema. When this has returned a second is administered, but consisting solely of a quart of cold water. Absolute rest on the bed is enjoined; while cloths dipped in cold water, or, better still, bladders of ice-cold water, or pounded ice, are applied to the anus, perineum, thighs, and hypogastrium. If the patient do not void his urine in the course of half an hour, or void it only very scantily, he is placed at the edge of the bed, which is properly guarded, and a stream of cold water is poured on the region of the bladder during from twenty to twenty-five minutes. After the lapse of this time another enema of cold water, and small smooth fragments of ice, are introduced into the rectum, the cold applications to the external parts being at the same time continued. The cases in which this mode of treatment is found applicable are those in which the retention proceeds from acute inflammation or spasm.

Reviews.

Pathological and Surgical Observations on the Diseases of the Joints. By SIR BENJAMIN C. BRODIE, Bart., V.P.R.S., Serjeant Surgeon to the Queen, Surgeon to H.R.H. Prince Albert; formerly Surgeon to St. George's Hospital, &c. &c. Fifth edition, with alterations and additions. 8vo. pp. 399. London: Longman and Co. 1850.

THE publishers of the new edition of this well-known work have appended to its author's name the highest titles of honour to which the greatest surgical talents can lead their possessor in this country. The fame of Brodie, however, will always be more closely connected throughout the world with the work itself, than with these merely honorary dignities. The first edition of this work showed an author of close reasoning powers, endowed with a more than common share of those qualities which contribute to form the skilful surgeon. The fifth edition finds the opinion then formed to be correct, and its author elevated by the conjoint approbation of his profession and of the public, to the most exalted point of professional success; the enjoyment of the highest honours and emoluments that industry and ability are capable of commanding. Of Sir Benjamin Brodie it may be said with truth, even at the present time, "*Actis ævum implet, non segnibus annis;*" and we would add, long may he live to reap their just reward.

We cannot better introduce the fifth edition of this invaluable work to our readers than in the words of the author himself:—

"The fifth edition of my treatise on the diseases of the joints, which is now offered to the public, differs, in many respects, from those by which it has been preceded. I have found no reason to alter the general arrangement of these diseases which my early investigations had led me to adopt. But many new cases and observations have been introduced, illustrating the pathological changes which were described formerly; and some new chapters have been added, relating to other changes, which my earlier experience had led me to notice only in a brief and cursory manner. Those parts, which relate to the diagnosis and treatment

of diseases have been considerably extended, and I hope that the volume will thus be rendered more useful to the practical surgeon, whose principal object must always be to obtain the means of cure, and to whom scientific pathology will be valuable in proportion as it leads to this ulterior result.

"Although these researches have occupied more or less of my time during the greater part of my professional life, I am aware that they are still imperfect. When I first turned my attention to the subject, I found that I was engaged in a new and extensive field of inquiry, such as it was impossible for one individual, however diligent, and however great his opportunities, thoroughly to explore. Those who follow me will, I doubt not, find much both to add and to correct; but I trust that what I have been able to accomplish will assist them in their labours, and will, in the meanwhile, in some degree supply what was formerly a great deficiency in the literature of scientific surgery. In the earlier editions I published a series of cases illustrative of the history and progress of the various diseases of the joints, as they are exhibited in the living person, and the treatment which they require. I was led to do so, as the subject was at that time, in a great degree, new to my readers, as it had been to myself. Under present circumstances it has appeared to me that another course was to be preferred, and I have accordingly endeavoured to supply the information which it was thus intended to convey, in the form of a more complete analysis of the observations which I have made in the course of my practice, omitting the details of individual cases, with the exception of those relating to pathology."

The subjects treated in this volume are nearly the same as those contained in the preceding editions of the work. We shall enumerate its contents, in order that our readers may compare this edition with its predecessors. At the same time we must remark, that a close study alone of the work itself will show the extent of the additions.

"Inflammation of the synovial membranes of joints. Ulceration of the synovial membrane. Cases in which the synovial membrane has undergone a morbid alteration of structure. Scrofulous disease of the joints having its origin in the cancellous structure of the bones. Ulceration of the articular cartilages. Necrosis of the joints. Chronic disease of the joints connected with gout and rheumatic gout. Loose cartilages and excrescences in the cavities of the joints. Malignant diseases and other morbid growths connected with

the joints. Neuralgia of the joints. Chronic abscess in the articular extremity of the tibia. Caries of the spine. Some diseases of the joints not included under the foregoing heads. Inflammation of the synovial bursa."

The following observations, which occur in the first chapter, may well be borne in mind at a time when a manifest tendency exists to the too frequent reliance on topical remedies for what is often erroneously regarded as purely local disease. We have marked one sentence by italics, to direct especial attention thereto.

"Inflammation of a synovial membrane may arise as a local affection, the consequence of a sprain, a contusion, or other mechanical injury. In other cases, various joints being affected, either simultaneously or in succession, it is manifestly the effect of a disordered state of the general system; and even in those instances in which the inflammation is confined to a single joint, a careful inquiry will generally satisfy the surgeon that it has had a similar origin. *Indeed, I must confess that, in proportion as I have acquired a more extended experience in my profession, I have found more and more reason to believe that local diseases, in the strict sense of the term, are extremely rare.* Local causes may operate so as to render one organ more liable to disease than another; but every thing tends to prove, that in the great majority of cases there is a morbid condition, either of the circulating fluid, or of the nervous system, antecedent to the manifestation of disease in any particular structure." (p. 25.)

We would direct attention to Sir B. Brodie's opinion with reference to the opening of abscesses in the joints—a complication, often, of some general morbid condition, as scarlatina, puerperal fever, &c., constituting a symptom of very grave import, and, from the concurrent effects of disease, one extremely difficult to cope with.

"As a general rule, I believe that it is advisable to open an abscess connected with a diseased joint, rather than to allow it to burst spontaneously; but the opening should be deferred until the skin is become thin over it, except in a few cases in which it is burrowing among the muscles of the limb under a thick fascia. There are few questions in surgery of greater practical importance than that which relates to the management of an abscess connected with a diseased joint. There are great objections to the opening the abscess by a small puncture. Even if the

orifice should not (as frequently happens) become obliterated by portions of solid lymph impacted in it, neither at the time of its being made, nor afterwards, does such a puncture afford a free passage for its contents. A certain quantity of pus accumulates in the cavity of the abscess, the overplus escaping through the artificial orifice as the overplus of water escapes through the waste-pipe of a cistern. Under these circumstances the purulent discharge is invariably profuse; for a lodgment of pus operates like a pea in an issue, by stimulating the secreting surface, and augmenting the secretion.

"The practice which has appeared to me to be, on the whole, the best, is the following:—An opening having been made with an abscess-lancet, the limb may be wrapped up in a flannel wrung out of hot water; and this may be continued until the first flow of matter has ceased, a poultice, or warm water dressing, being applied afterwards. In some instances, after a short time the discharge ceases, the orifice heals, and the puncture may then be repeated some time afterwards. But where the puncture has not become closed, I have never found any ill consequences to arise from its remaining open. On the contrary, I have no doubt that it is desirable that the wound should not be closed until the abscess has contracted, granulated, and healed from the bottom; and this is one reason for making, not a small puncture, but a free opening with an abscess-lancet. Another reason is, that the matter will escape readily without squeezing or pressure. *All rough manipulation is to be carefully avoided.* It produces hæmorrhage into the cavity of the abscess, the ill consequences of which I have already pointed out; and, independently of this, it may excite inflammation of the cyst, attended, where the surface is extensive, with so much constitutional disturbance as to endanger the life of the patient at the time, and materially lessen the chance of his recovery afterwards." (p. 133–137.)

The following remarks on a subject of much diversity of opinion deserve notice, as showing harmony between the results of practical experience and scientific research.

"If a section be made of the articular cartilages in a growing child, canals or sinuses may be distinctly perceived in them, containing red blood. These are not constructed with the distinct tunics of ordinary blood-vessels, nor is there any appearance of minute ramifications of vessels pervading the cartilage generally. Still it would be unreasonable to doubt that they are intended to convey blood into these

structures for the purposes of nutrition and growth.

"But after the period of growth is concluded, no blood-vessels can be detected in healthy cartilages, even on microscopical examination; and as modern researches in anatomy have shown, that not only nutrition, but absorption, and various changes of structure, may take place in the living body, independently of any distinct vascular apparatus, we are justified in the conclusion, that under the circumstances which have been just mentioned, no such apparatus exists."

After allusions to the observations of Messrs. Mayo and Liston, Sir Benjamin proceeds to remark:—

"Interesting as these observations may be, as to the vascularity or non-vascularity of cartilages, and the mode in which the changes which they undergo in health and disease are produced, and important as the researches in minute anatomy, conducted by means of the microscope, may ultimately prove to be, it must be acknowledged that the time has not yet arrived at which the results can be applied, with much advantage, to the advancement of practical surgery. In whatever way it may be accomplished, whether by the development and destruction of cells, or by means of capillary vessels, or partly by one and partly by the other, there is no doubt that cartilages are nourished and grow, and undergo changes of organization, and that they are absorbed and die, and exfoliate, very much in the same way as parts which are distinctly vascular. And after all that can be said on the subject, the difference in these respects between cartilages and the other animal structures is probably more apparent than real. There can be no more doubt that the former derive new materials in some manner from the vessels of the bone to which they are attached, and that their old materials pass into the general circulation through the same channel, than that the fetus somehow receives its nourishment from the maternal portion of the placenta. Nor should we lose sight of this consideration, that even in those organs which are endowed with the highest degree of vascularity, it cannot be supposed that every change that takes place is by the distinct agency of blood-vessels. The latter supply the new materials, but they cannot occupy every point of space, and there must be intervals between them in which it is probable that molecular changes are taking place, corresponding to those which occur in what are called extra-vascular organs." (p. 155.)

It is almost superfluous to remark

that these observations correspond with the results of the latest microscopical investigations into diseases of the cartilages.

One subject with which Sir Benjamin Brodie's continuous labour, and later observations, have enriched surgical science, is the pathology of certain obscure cases of disease about the knee-joint, in which, doubtless, amputation may have needlessly been had recourse to, but which Sir B. Brodie has shown to be curable by the use of the trephine alone: this disease is chronic abscess in the head of the tibia. We shall quote a portion of the author's remarks on this disease, which requires great nicety and judgment in its detection and treatment.

"Occasionally, chronic inflammation of the articular extremity of the tibia terminates in the formation of an abscess in the centre of the bone, but contiguous to the joint. An abscess of this kind is attended with an extraordinary degree of suffering, such as not only would justify amputation, if there were no other means of obtaining relief, but would induce the patient cheerfully to submit to the operation. Fortunately, a less formidable mode of cure is within our reach." (p. 288.)

"Chronic abscess of the extremity of the tibia may exist during a very long period before it interferes with the neighbouring joint. In one case the patient had laboured under the symptoms of the disease for as many as eighteen years before I was consulted. The symptoms by which the disease is indicated in the first instance, is pain in the affected part, which is more or less of an intermitting character. The pain gradually becomes more severe, but still it is intermitting. For some time the patient may suffer so little from it that he is not prevented from attending to his usual occupations; then, without any manifest reason, a paroxysm occurs, in which the pain is intense: he is utterly disabled, and even unable to quit his bed. This gradually subsides, and he has another interval of ease. As the disease goes on, the bone becomes increased in size, the general health becomes affected, and the mind probably is rendered miserable and irritable by long-continued suffering. In one case, whenever the patient began to use the limb, the knee itself became inflamed, and there was an effusion of fluid into the cavity of the synovial membrane." (p. 286.)

"The most important point in the operation is that of ascertaining the exact part at which the trephine should be applied. I have always found that there was one spot to which the pain was more especially re-

ferred, and which was more especially sensible to pressure; and, when this has been satisfactorily determined, I have concluded that this was the part at which the perforation should be made. The trephine which I have generally used is a little more than half an inch in diameter, and is without any projecting rim, so that there is nothing to prevent it penetrating to any depth that may be required. Sometimes, when I have taken out a portion of the bone by means of the trephine, I have found it expedient to make use of a common elevator to complete the operation, by breaking down the immediate boundary of the abscess; but I have never yet had occasion to make a second application of the trephine. However, such an occasion may occur. A very experienced hospital surgeon applied the trephine for a supposed abscess in the head of the tibia. No abscess, however, was discovered; and, in consequence, the limb was amputated. On the parts being examined afterwards, the abscess was discovered at a small distance from the perforation made in the operation; and it was plain that the removal of a small portion more of the bone would have preserved the patient's limb." (p. 298.)

The work we have here brought before our readers needs no commendation from the pen of a reviewer. Its position in surgical literature is fixed. We would merely impress upon all those whose library-shelves do not possess a copy of this treatise, that whether physicians or surgeons, whether "pure" or "general practitioners," their libraries are deficient in one of the latest and best models of what medical researches should be. The senior members of our profession will find herein practical reminiscences of their own experience; while the junior will find an example which they may wisely follow, whatever may be the subject of their studies and researches. May they pursue them, like Sir Benjamin Brodie—*fortiter, fideliter, felicitèr*.

The Sumbul: a new Asiatic remedy, of great power, against Nervous Disorders, Spasms of the Stomach, Cramp, Hysterical Affections, Paralysis of the Limbs, and Epilepsy: with an account of its physical, chemical, and medicinal characters, and specific property of checking Collapse-cholera, as first ascertained in Russia.
By A. B. GRANVILLE, M.D. F.R.S.,

of the Royal College of Physicians, London, &c. &c. Pamphlet, 12mo. pp. 40. London: Churchill, 1850.

"SUMBUL is the Asiatic name of a vegetable drug, hitherto nearly altogether unknown to the medical practitioners of Europe. It is only within the last two years that in some parts of the Continent it has acquired considerable celebrity, in consequence of its ascertained value in the worst stages of CHOLERA."

Dr. Granville thus introduces the subject of his pamphlet. He informs us also, that "previously to such application of the drug, the Sumbul had been employed in Russia, as a stimulant and rouser of animal energy in the advanced stages of malignant fevers, (Typhus); as well as in dysentery of an asthenic or debilitating character, not less than in chronic diarrhoea, with unquestionable success."

The information which the author has been able to obtain on the *habitat* and character of this plant is very imperfect. But there is every reason to believe that the plant belongs to the umbelliferous family, and that it is probably an aquatic plant. Dr. Granville mentions two very striking physical characters, its "perfume like that of the purest musk, and the powerful aroma it exhales in the mouth when masticated," which is very peculiar, somewhat resembling that of *Angelica* root.

Chemical analysis gives as its constituents; water, an ethereal oil, two balsamic resins, wax, aromatic spirit, and a bitter substance.

The classes of diseases for which it has been employed are indicated on the title-page, which we have copied above.

The author adds "A Few Words on the question of Cholera;" in the collapse of which Dr. Granville asserts that Sumbul has been found pre-eminently efficacious. We rejoice to know that at present we have no opportunity of trying this new remedy for the last-named disease. In other forms of disease its virtues will doubtless soon be ascertained, if they are not extravagantly lauded after the fashion of "certain cures" for all cases of "consumption, asthma, coughs, colds, shortness of breathing," &c. &c.

Proceedings of Societies.

ACADEMY OF MEDICINE, PARIS.

July 30, 1850.

New Speculum for the Mouth.

M. MATHIEU submitted an instrument which has the advantage of being placed in the mouth without the necessity of its being previously opened wide for its admission; and which does not obscure any portion of its cavity, nor impede operative proceedings.

Gutta-percha Instruments.

M. ROBERT read a report on a memoir presented by M. Gabrol, which spoke in favourable terms of the employment of gutta-percha for the manufacture of many surgical instruments. M. Ricord agreed with the report, with the exception that he did not concur in the opinion that the use of gutta-percha sounds disposed, less than others, to the formation of calculous deposits. These, M. Ricord observed, are dependent upon individual peculiarities, and not upon the introduction of instruments. M. Ricord considered sounds and bougies of gutta-percha to be more durable, and superior to those of caoutchouc or wax.

M. Velpeau had found gutta-percha bougies to yield when warmed by contact with the walls of the urethra, and from their want of elasticity lose their shape. The same inconvenience, M. Velpeau stated, had attended the use of gutta-percha pessaries.

M. Segalas had found these sounds and bougies an improvement upon those formerly in use.

SURGICAL SOCIETY OF PARIS.

July 31, 1850.

M. HUGUIER stated that the microscopical examination of the cutaneous tumors submitted on a former occasion had confirmed the opinion of M. Giraldes, who considered them to be simple hypertrophy of the skin. The polypus of the rectum, which also was exhibited on a previous occasion, had been examined microscopically, and found to consist of thickened mucous membrane and fibrous coat of the intestine.

Fatal Vesical Hemorrhage.

M. VIDAL read a report on a work by M. Desormaux, in which a case was related of a man who, in otherwise good health, died

from hemorrhage into the bladder. That organ was found filled with coagulated blood, in the midst of which was a small calculus. No disease of the bladder, prostate, or urethra, could be found to account for the hemorrhage; but, as M. Vidal observes, the kidneys and ureters not having been examined, who knows whether the kidney might not have been its source?

ACADEMY OF SCIENCES, PARIS.

July 29, 1849.

Antidote for the Bites of Serpents, &c.

M. JOMARD submitted, in behalf of M. HERRAN, *Chargé d'affaires* in France, of the Republic of Costa Rica, a number of grains yielded by a tree which is called in that country *Cedron*, and grows on the Cordillera of the Andes. These grains are said to be antidotes to the bites of venomous serpents, &c. They are used in doses of five or six grains, given internally in brandy, and a small portion of their powder is at the same time applied to the wound. M. HERRAN, in desiring that the properties of these grains should be investigated, stated that he had also employed them with success in cases of ague that had resisted quinine.

Veterinary Surgery, &c.

M. BAYEN described a new method of removing the ovaries of calves by an incision through the superior part of the vagina, which had been found successful, and was not followed by peritonitis.

M. LUTERIE (of Rambervillere), informed the Academy that he had observed epidemics of influenza attacking horses, with, in every respect, the same symptoms as occur in man.

DURHAM COUNTY MEDICAL ASSOCIATION.

AN influential meeting of the members of the medical profession belonging to the city of Durham and the surrounding neighbourhood was held last week at Durham. W. Green, Esq., presided on the occasion: and it was unanimously determined that an Association should be formed, to be called "The Durham County Medical Association for the prosecution of unqualified Practitioners, and for the suppression of Quackery in all its forms, whether in the Profession or out of it." Resolutions respecting the qualifications for membership and other matters were passed; and after Mr. J. Patrick had been appointed the solicitor and secretary of the Association, the meeting was adjourned until Monday, the 5th of August.

Hospital and Infirmary Reports.

FELLOWS' PRIZE REPORTS
OF
CASES OCCURRING IN UNIVERSITY COLLEGE
HOSPITAL.

Summer Session 1845.

By C. H. F. BOUTH, M.D. Lond.

[Continued from p. 189.]

Autopsy, twelve hours after death.—Temperature 70° Fahr.

The body was greatly emaciated. Skin very pale. Abdomen prominent; integuments over it somewhat discoloured. Lips and cheeks very pale also. There was a slight abrasion of the skin over the left knee-joint; no oedema or rigor mortis. Muscles pale and flabby.

The brain was not examined.

On opening the trunk, the lungs were found collapsed. The liver seemed to extend about one inch below the margin of the ribs. The abdominal contents found to be closely agglutinated together by recent lymph, containing about $\frac{3}{4}$ viij. of serum. About three or four inches above the margin of the pubis a perforation of the small intestine was visible. About one or two inches above this, two other spots, where the peritoneal covering alone was entire. Around the complete perforation before noticed, some fecal matter was found to have escaped in the cavity of the abdomen. These appearances, however, will be more closely described immediately.

The left pleura contained about $\frac{3}{4}$ j. of fluid. The left lung itself was soft and pale, studded with tubercles of recent formation, soft, plump, and pale in colour. There were several small cavities at the apex, about the size of small beans, containing broken-up yellow tubercle. In the lower lobe several small clustered tubercles existed, with congestion around them.

The apex of the right lung was firmly adherent. There was a large cavity, about the size of a pigeon's egg, and two or three smaller openings into it, containing a little grey softened tubercle, but no large bronchi entering into it. The apex to the feel was consolidated, and the substance of the lung at this part, except the innermost portion, appeared to be infiltrated with solid matter. The inner surface of the apex was of a dark grey colour, with scarcely any tubercle. The middle lobe contained also a large cavity: the lower lobe was thinner,

and also contained soft tubercle. Weight 3iv½.

Some of the bronchial glands were tuberculous, others not, and several containing carbonaceous matter, with a little cretaceous grit.

Heart was small; left ventricle somewhat contracted. The right auricle contained a polypus. Otherwise the structure of the heart was healthy. Weight 3viii.

On examining the *abdomen* more carefully, the intestines were found to be all agglutinated, of a greyish yellow colour; but the adhesions appeared recent, and could be readily torn through. A quantity of fine granular tuberculous points were found studded over the peritoneal surface, varying from the finest points to the size of large pins' heads, or small peas; over the peritoneal surface covering the right kidney they were larger. In the right iliac fossa there were 3ij. to 3iij. of fetid muddy-looking serum, on removing which four patches of ulceration were seen in the ilium, two of which had opened in the peritoneal sac, and allowed the contents of the gut to escape. Situated opposite, about the middle of the transverse ramus of the pubis, there was an adhesion, which, on being severed, exhibited an ulceration of the intestine at this part, which had proceeded to perforation. The upper surface of the liver was adherent to the diaphragm; the intestines generally so soft as to tear with the slightest force.

The *liver* contained a good deal of bile. The under surface was of a dark slate colour; the upper surface was studded with fine granular tubercles, but which appeared to be confined to the capsule, and not in its substance, as they came away easily, and could be separated with it. The pale spots of the liver were of larger size than usual, and the structure generally coarse, and otherwise unhealthy; the upper surface generally softer than the under. On cutting through the substance of the liver there were here and there some white spots, which at first resembled tubercle, but on closer inspection appeared to be only branches of the portal vein, cut through, thickened and tinged with bile by the biliary duct. The gall-bladder was full of bile. Weight 3lbs. 3xiv.

Kidneys.—Left supra-renal capsule much larger than usual. The upper surface of the left kidney had a little the appearance of coarse mottling, and here and there slight points of cacoplastic deposits in a separate form. The structure of the kidney was generally coarse. Weight 3iv.

The peritoneal surface of the right kidney was covered with tubercular deposits, varying from the smallest size to that of a hemp-seed. The upper layer of the capsule

was not adherent; the under was quite so, and could not be removed. The texture throughout was coarse. Weight 3vss.

The *spleen* was quite healthy, only a little larger than usual.

The stomach.—The organ appeared somewhat opaque, and the surface a little softened. The isolated pyloric glands were more conspicuous than usual, but there were no signs of inflammatory redness or ulceration about the mucous membrane.

Small intestines.—The ulcerations began in the duodenum, and there was an immense mass of hardened mesenteric glands filled with tubercular matter attached behind.

At the lower end of the ileum the peritoneal covering was found to contain in its substance several tubercular masses, which could be turned out, and were cheesy-looking in appearance. In addition, there were many opaque patches, with recent and tuberculous granular matter. These patches, in by far the greater number, corresponded to ulcerations within the gut, and *portions could be traced along the vessels*.

The internal mucous membrane presented the following appearances:—

Beginning in the duodenum there were several separate ulcers, varying from the size of a bean to two inches in length, and one broad. These ulcers were situated at the portion where the mesentery is attached, and spread transversely to the axis of the intestine. In no parts of the ileum or jejunum was there three inches of the intestinal tract free from them. The edges of some of these were quite pale; others, again, were more vascular. Some of the edges, again, were quite hard, and appeared to consist of tuberculous matter still remaining. In most of these, the mucous, submucous, and muscular coats, seemed to be completely eaten through by the ulceration, the peritoneal only remaining entire. Where perforation had occurred, the edges of the peritoneal surface corresponding were ragged. In some of the ulcers, especially the smaller, the edges of the tubercular mass were seen softening, the tubercle existing in largest quantity in the neighbourhood of the colon.

Large intestines.—The ilio-colic valve was remarkably ulcerated, and of a dark colour. At the commencement of the ascending colon there were three patches of ulceration—one about two inches by one, just above the valve; another four inches lower down, of the same size; and the third about the size of a bean, in position intermediate between the two others; *the long diameter of all the ulcerations was placed transversely to the axis of the intestines*. The rest of the colon was remarkably free

from ulcerations or cicatrices; indeed, quite healthy.

The clusters of mesenteric glands attached were all in a tuberculous state, varying from the size of half a hen's egg to that of a pea. Some of these were quite of a cartilaginous hardness.

The bladder was full of urine, high-coloured, sp. gr. 1018; no albumen. The upper portion of the ascending aorta contained a fibrinous clot of a quantity of dark black fluid blood. There were no eacoplastic deposits in any part of it, or in the iliac arteries.

Microscopical Appearances of the Tubercles. Examined by Dr. C. J. B. WILLIAMS. (400 diameters.)

No. 1.—Cut from the yellowest part of a cluster of miliary tubercles taken from the left lung.—It contained clustered granules of irregular shape and size, with a few long waving fibres here and there to be traced amongst them.

No. 2.—Squeezed from the softest part of

a solid yellow tubercle in the left lung.—Granules clustered, as in No. 1, but without any trace of fibre, and a few more oil globules, breaking down readily with water.

No. 3.—Squeezed from the centre of a yellow mass in the mesentery.—Same appearances as No. 2.

No. 4.—Cut from a semi-opaque granulation in the peritoneum over the right kidney.—Granules closely impacted in a few fibres.

No. 5.—Cut from an opaque granular deposit under the peritoneal surface covering the small intestine near an ulcer.—The same as No. 4, but with less trace of fibres.

There was no appearance of pus globules in any of the five specimens examined.

I had also an opportunity of examining under the microscope several portions of the tubercles, and they agreed in every respect with Dr. Williams's account. I only observed, however, the fibres very distinctly in one specimen, and that taken from the lung.

REMARKS.—The above is a most interesting case of perverted or mal-nutrition, well illustrating the influence of such a state in determining the formation of aplasia and tuberculous matter, where, under ordinary circumstances, lymph would have been effused.

Diagnosis.—The principal complaints made by this patient on his admission had reference to his stomach. He experienced here a feeling of uneasiness, sometimes amounting to severe pain, after eating. There was tenderness at the epigastrium, nausea, loss of appetite, flatulence. These symptoms might be referred to three conditions of the stomach—1st, simple gastrodynia, or gastralgia; 2d, chronic gastritis; 3d, organic disease.

Now, the present symptoms were more those of gastritis, in the early history of the case perhaps it was only gastrodynia, the pain being relieved by warm drinks. Now, however, the reverse was the case: warm drinks increased, but cold relieved the pain. These are symptoms of gastritis. Moreover, the tongue was dry, red, and lobulated: in gastrodynia it is usually pale and furrowed, and may be moist. It has moreover an oedematous kind of look, not here remarked. Moreover, the nature of his occupation was such as might give rise to chronic gastritis. His gums had a blue line upon them, which an excess of lead in the constitution produces. Now one of the properties of lead is that of an irritant poison. There was, moreover, very much thirst. There was therefore very clearly gastritis present; yet it could not be considerable. The pulse was not quickened; the skin was cool and moist; and there was no actual vomiting.

But there was also certainly something more than mere gastritis. Here was a patient very much emaciated, with the abdomen very prominent and large. Moreover, there was habitual costiveness. By reference to the previous history, moreover, there had probably been melæna. Here were marked symptoms of organic disease. Was it, however, tuberculous or cancerous? First, in regard to the latter supposition: no tumor or ulceration could be detected in the stomach; and, although his face was sallow, yet it did not bear the marked sallowness of cancer. It is true, in tabes, the stools are not usually bloody; but where ulceration co-exists in the intestine, even in tabes this result would necessarily be observed. Moreover, the thoracic symptoms were rather those of tubercle than cancer. There were some signs of consolidation in the upper lobe of the right lung. It was duller on percussion, and the expiration was too loud. The pain on respiration or dyspnoea was trifling. Now cancer of the

lung is a very rare disease; and in cancer, moreover, the dyspnoea is usually more marked, and the pain greater. Then his hereditary predisposition might be considered as phthisical. His father died from bursting a bloodvessel (phthisis?). In addition, he had been exposed to causes favourable to the production of tuberculous growths.

On the other hand, his father's death might have resulted from hæmatemesis. He himself denied his family were consumptive or scrofulous. His pulse was natural as regarded frequency; he had never had hæmoptysis; nor was he liable to coughs.

Yet, while it could not be positively stated he had not cancer of the lung or stomach, the weight of evidence seemed to be on the side of tubercle.

II. There was also some hepatic congestion, as indicated by the increased dullness on percussion over this region.

Treatment.—The indications were threefold—1st, to regulate the bowels, the continued constipation of which might have had a considerable share in the production of the gastric symptoms; 2d, to palliate, and, if possible, to remove the gastric affection, by direct means; 3d, the extreme weakness and emaciation of the patient implied the necessity of supporting him, as well as of improving the general tone of his habit. This, however, could not be attempted until the second indication was fulfilled, and the irritability of the stomach in some measure subdued.

To fulfil the first indication, he was purged with calomel and colocynth, and castor-oil at different times. To fulfil the second, prussic acid and carbonate of soda given. This mixture experience has shown to be peculiarly serviceable in cases of gastralgia, or chronic gastritis, and not only to lull the pain, but also the general sensibility, and thus to give time for the use of measures more calculated to produce a permanent impression upon the system. To fulfil the third, he was first put upon low diet, which, as the gradual improvement in the stomach symptoms took place, was superseded by middle diet, and finally a chop daily.

But the complication of organic disease could not be overcome; and thus, although the treatment employed was so successful that all pain at the stomach ceased, the sensation of fulness after eating disappeared, the liver resumed its natural size, the night sweats were less copious, and he was even enabled to get up,—still the organic disease progressed with fearful strides both in the lungs and stomach, and very soon all hopes of his recovery were given up.

First the castor-oil seemed to disagree with him. This is by no means an unusual occurrence. With some persons it always produces these results. The pain in the stomach returned, though perhaps it was not quite so bad as on his admission.

The symptoms on the 5th were peculiarly interesting. It was observed the *vocal fremitus* was transmitted through the abdominal parietes. This would necessarily imply a direct solid communication between the lung and the abdomen, through which the sound could be continuously conveyed. The most probable explanation was the presence of tubercle in the lungs; and tabes mesenterica. The enlarged glands, however, could not be then detected, owing perhaps in a great measure to the tympanitic state of the abdomen; nor did the examination of the back, by making the patient lie on his belly, throw any more light on the diagnosis. The examination made on the 8th, however, did, and was conclusive as to the increase of the tubercular disease in the lung. At first, as has been seen, the right side had been duller than the left; then, however, the expiration was only heard. Now, however, both in front and behind, it was tubular. The resonance, it was true, was still considerable, but his extreme emaciation explained this. As the pain at the stomach was no better, a blister was applied, and the dose of the hydrocyanic acid increased. It is interesting to note, that notwithstanding the serious complications that occurred subsequently in the course of this patient's disease, yet that as a result of this treatment no pain was again felt after eating, and the only inconvenience was occasionally a little fullness. As the case progressed, however, other more unfavourable symptoms presented themselves. One of these was sleeplessness, to remove which, first hyoscyamus, subsequently morphia, were given, but with little benefit. His debility and emaciation increased. Aphthae were formed on his tongue and inside his cheeks, depending, no doubt, on the general atony and cachexia present. Bark was therefore given.

On the 15th his countenance began to assume a very peculiar expression; thoroughly deprived of the slightest anxiety, and expressive of the greatest indifference. This character of the countenance we have noticed on several occasions where most extensive organic disease was present. Symptoms of tubercular peritonitis accordingly soon presented themselves. Ascites without pain occurred. On the 16th those of ulceration of the intestines were superadded: a large quantity of blood was passed by stool. From its appearance, most of it being dark and pitchy, it was inferred the greater part came from the upper portion of

the intestinal tract. The presence, however, of clots of a more florid colour also seemed to indicate that some of it might also come from the lower portion of the small intestine, or upper part of the lung. The question again presented itself—was it carcinomatous or tubercular ulceration? In support of the first there was only the foetid odour which was supposed at the time to resemble that of cancer. What, however, has been said before, applies equally well here again. The weight of evidence was in favour of tubercle. In tabes mesenterica, moreover, the stools are very offensive.

On the 17th the hemorrhage again recurred, and for the first time, owing to the less tympanitic state of abdomen, something like a tumor was detected in the region of the pylorus. Now here was a puzzling symptom, supposing the diagnosis above given to be correct. Could this not have been cancer of the pylorus? But the negative even here seemed to be the more probable opinion. Cancer of the stomach usually produces sickness and vomiting; pain, moreover, is at this advanced stage almost invariably present. 2. This tumor might simply have been enlarged mesenteric glands, which M. Guersant believes is a disease equally common in the adult as in the child. Moreover, the same objections before made applied with equal force at present.

The blood evacuated on the 17th was less pitchy. As, however, it contained but very little fecal matter, it was thought advisable to give him a gentle purgative. This put him to severe pain. On the 21st diarrhoea set in, with copious loss of blood. At one time, moreover, most acute pain was felt at one spot, accompanied with great faintness, which lasted two hours. Under the influence of wine, but particularly of opium, he was recovered and relieved for the time. Viewing this symptom in connexion with his previous sufferings, it appeared probable that perforation of the intestine had occurred; and it is interesting to note here the beneficial effect of the opium, given even in small doses, in relieving this pain for the time. The same night, however, a second perforation seems to have occurred, in which the collapse was more marked, and which proved fatal. Throughout the patient's illness there appeared to be no disease of the kidney. The urine was sufficient in quantity; the excreted solid matter not defective, and bearing a fair proportion to the ingesta taken. Purpurine, so often detected in phthisis, was absent. The urine, indeed, gave with nitric acid some abnormal blue reactions; but when heated it was unaffected by hydrochloric acid. Uric acid crystals were present; but dyspepsia is a

common cause of their occurrence, and their presence, therefore, in no way facilitated the diagnosis.

The post-mortem appearances were full of interest.

1. *Tabes mesenterica* was found, and advanced even to the state of ulceration. The insidious nature of the attack is curious. During the first weeks of his residence in the hospital the symptoms were almost entirely confined to the stomach. After death this organ appeared least affected; there might indeed have been a slight amount of inflammation of the mucous membrane, as indicated by the somewhat opaque rugae and softening; but the inflammation in the intestines was probably then also equally and even more advanced, and yet they were remarkably free from pain, and all diarrhoea was absent. Either, therefore, we must suppose that the ulceration and inflammation of the intestines only occurred at a late period, and progressed with great rapidity, to account for the absence of pain at first; or that the disease was in some respects masked by the presence of lead in the system, producing constipation, and thus accounting for the absence of diarrhoea.

2. In relation to the phthisis present. If we except the emaciation, and hectic, and the night sweats, all of which might have been produced by the *tabes*, the symptoms of phthisis were certainly less marked during life than we should have been led to expect from the post-mortem appearances. There was no cough or dyspnoea. There had never been any hæmoptysis. The pulse was remarkably slow and regular. Moreover, the dulness was never very great, though sufficient to denote disease in the upper lobes of both lung. This is explained by the degree of emaciation. Two cavities were found in the right lung. The respiration had never been cavernous or gurgling during life; simply bronchial, and that only towards the last days of his illness. The rapidity with which the disease progressed may explain this in some measure. Perhaps, had he been examined on the day of his death, it had been cavernous; but apart from this suggestion, there can be no doubt Laennec laid too much stress on cavernous respiration as being always present where a cavity existed. All the signs of a cavity may be present, and yet there may be no cavity, and vice versa. A simple bronchus abscess, surrounded by consolidated lung, will give rise to cavernous respiration, especially if a large bronchus, and in the neighbourhood of the trachea, from which indeed the sound may be occasionally transmitted. Moreover, if no large bronchus open in a cavity, and more especially if the cavity be not very large, no ca-

vernous respiration will be heard. This was the case here.

3. We have already noticed more than once the transmission of the vocal fremitus through the abdominal walls. The post-mortem appearances explain satisfactorily this phenomenon. The posterior part of the lungs was consolidated, along the spine, continuously with the enlarged mesenteric glands, which, by their projection anteriorly, and connexion with the liver, afforded a continuity of solid matter to the abdominal parietes for the transmission of sound.

4. The extreme rapidity with which the disease progressed, though already more than once incidentally alluded to, may be especially insisted upon as most remarkable in this case. No case could more beautifully illustrate the occurrence of disease from perverted nutrition, and the insidious nature of such affections generally, with so few prominent symptoms, so that scarcely a portion of the vital organs shall remain unaffected, and yet the patient, till but within a very few days of his death, shall not complain; so little do material sensations or mental feeling appear to be connected with it.

Causes.—I. *Predisposing.* Of the gastric affection; a. The previous attack of dyspepsia. This, by debilitating an organ previously healthy, would render it more obnoxious to a second attack.

b. *Imperfect nourishment.* While a confectioner he had eaten at very irregular intervals, and chiefly articles of confectionary. Lately, since his misfortunes, his food appeared to have been bad in kind.

c. His occupation as a painter. Lead is also an irritant. Moreover, painters generally are liable to disorders of the nutritive functions.

d. His residence damp and close.

e. *Mental anxiety*: a very powerful debilitating cause.

f. *Hereditary predisposition.*—His father probably died of phthisis. All these causes, by affecting his strength, and weakening his constitution generally, would equally act as predisposing causes to the occurrence of the tubercular affections in the lungs and abdomen.

Exciting cause.—The general opinion at the present day of the occurrence of *tabes mesenterica* seems to be, that the glands only become affected after the mucous membrane has been so. This man certainly appears to have suffered first from gastritis, probably also from the inflammation of the mucous membrane of the intestines. This primary affection may therefore be considered as the exciting cause of the *tabes*.

In accordance with Louis' remark, the abdomen being affected with *tabes*, the

lungs were also found diseased. How far the one might be considered as the effect of the other, does not appear. No distinct exciting cause, except the combined influence of the predisposing, could be traced.

Proximate causes and pathology.—This was a disease developed in its purest form. It was albuminous granular matter, destitute of cells and fibres, which form the true matter of organization. The plasma of the blood was too degraded to form part of living structure, therefore injuring those parts on which it was effused, and causing obstruction.

2. The situation explained further the rapidity of its progress. The deposit took place chiefly in the intestinal canal and mesentery; thus, by attacking and impeding the functions of the principal organs of nutrition, causing starvation of the body.

3. This defective nutrition will in some measure account for the pain and inflammation being so disproportionate to the amount of disease present. The distressing and harassing symptoms of many cases of phthisis do not depend on tubercle alone, but chiefly on congestion and inflammation of the surrounding parts. Withdraw this inflammation or congestion, as by derivants, counter-irritation, local depletion, the symptoms are at once alleviated. Here, however, the blood was so poor in quality, and so deficient in plastic material, that the inflammation was therefore but very limited. Although in his case the most formidable lesion that can occur was present, perforation, its symptoms were by no means well marked, perhaps from the same reason. The inflammation (if indeed it might not rather be considered a non-inflammatory softening) that gave rise to the original ulceration, was trifling and very limited, probably from the same cause.

Prognosis.—The suspicion which existed from the first as to the presence of organic disease was unfavourable: as, however, he at first appeared so completely to improve, it was hoped he might have recovered at least from his present attack. This hope, as the case progressed, was soon abandoned. The fearful rapidity with which both the abdominal and thoracic complications advanced, justified the most unfavourable apprehensions. The occurrence of the hæmorrhage assured a fatal termination.

THE CHOLERA AT MALTA.

LETTERS from Malta of the 28th ult. state that the cholera is somewhat on the decline there. Eight died of the troops sent to Fort Chambray, Gozo, and the same number are ill. The 44th Regiment has lost 65 men, 10 women, and 9 children. The 69th lost only one, a sergeant; the Artillery only three men.

Medical Trials and Inquests.

KILKENNY SUMMER ASSIZES.

July 1850.

Trial for murder by poisoning with corrosive sublimate—Local and general effects of the poison—Death in fifteen days—Solubility of corrosive sublimate in spirit—Mercury not detected in the body.—Conviction in the absence of chemical evidence.

[THE subjoined case is of great interest in medical jurisprudence. The mode in which the medical evidence was given is highly creditable to the gentlemen engaged as witnesses for the prosecution.]

Michael Walsh was charged with the murder of Simon Power, a bailiff holding a distress on his premises on the 30th August, 1849, by administering to him a deadly mercurial salt in whiskey. The prosecution was conducted by Messrs. Scott and Sansae; and the prisoner was defended by Messrs. Harris and Armstrong.

The general evidence for the prosecution established that the prisoner asked the deceased and a witness, Murphy, to take some whiskey. Murphy felt a pain in his stomach after swallowing about a tea-cupful, which was poured out for him by prisoner. In about ten minutes afterwards, prisoner called the deceased to him, and according to the evidence, the deceased must have taken a cup of whiskey, while alone with the prisoner.

In a few minutes, he became sick, and although able to walk home with Murphy, he was very ill. Murphy deposed that he did not perceive anything remarkable in the taste of the whiskey which he swallowed. The condition of the deceased (Power) is thus described by his daughter.

Anastasia Power examined—I am daughter of Simon Power; I remember his coming home from being keeping at the prisoner's; he came at six in the morning with James Murphy; he was vomiting; he went to bed; he continued very bad during the whole of that day; the vomiting continued until he died, in fifteen days afterwards; Dr. Boyd attended him a week after he was ill; he was very often sick and vomiting during that week; he was not able for that week to go about his business: every bit of him was sore; his mouth was sore and scalding, and the flesh inside his mouth would come away when he was spitting; I could pull out the flesh and it was black; his teeth were also black; the odour of his breath was most

offensive; the water from his mouth was green and thick; it was often coloured bloody; he complained of pains cutting him in the bowels, and of pains in his head; before he died lumps of lard like came from his stomach; the day he came home his cheeks were yellow; after some time his head and cheeks swelled up and became red; the middle of his tongue was white, and the borders red; he would start up when asleep and bawl as if in a fright; the first week his feet were warm and sore, and they got cold the last week. *Cross-examined*—

My father ate his supper on the night of Wednesday before he got sick; he ate peas for supper: he never went about his business after that Thursday. *Re-examined*—The supper of peas was a usual one.

To the Jury—My father had never had all those symptoms before; (he also had purging mixed with blood).

To the Court—During the first week he never went out; he never could have gone to Walsh's ground to keep.

Surgeon Boyd examined—I attended Simon Power; I saw him on the 6th of September: I prescribed for him on the 3d for a sore mouth; I found him lying in bed on the ground with a profuse flow of saliva from his mouth, with a most disagreeable odour; his tongue very much swollen, and partly protruding, indented at the sides and thickly coated; the gums were ulcerated, mouth generally swelled, with several whitish stains on it, with ulceration of the palate behind the teeth; the face was swollen and red; he complained of great inability to swallow; he could not eat, and spoke with difficulty; his pulse was excited; I got him taken out of bed to examine his body to see if he had been rubbing his body with ointment; I could detect nothing; I asked him if he had been taking medicine; he said not, but that that day week he got something from the prisoner in whiskey which was not right—that immediately after getting the whiskey he became sick—that he was not able to remain that day; that off and on he was in that day; that on swallowing the whiskey it had a very queer burning taste, and felt a burning in his mouth and throat: that about the third day his mouth became salivated and continued so; that he had a pain in his stomach; the chief pain he complained of was about the mouth and head, and he had never used any mercurial preparation, except four years before when he was in fever; that he had frequently drunk whiskey without any ill effects from it, and was in rude health before he took the whiskey; I saw him again on the 8th, 10th and 13th; the salivation continued, but the vomiting not so frequent: he was weaker on the 13th; there was a flow of blood

from his mouth on the 13th; from the symptoms I perceived I think he died from the effects of mercury; corrosive sublimate is a sort of mercury; it could have been administered by an ointment rubbed to the body, or by its being given in a drink; I consider it must have been administered to him in drink from what he said. *Baron Pennefather*—You are at liberty to say from the appearances or non-appearances whether you think it was administered externally or internally. *Witness*—I believe it was administered internally: corrosive sublimate is soluble in whiskey, and would not colour the drink, or have any smell; it would have a dry caustic taste, like as if a man got a taste of lime when in a kiln; from the symptoms, and from what the man said, I believe he came by his death from corrosive sublimate taken inwardly; it is a deadly poison; I made a post-mortem examination in order to send the stomach and its contents up to Dublin to be analyzed; a portion of the mouth was also sent up; the liver, kidneys, and spleen were sent to him on a second occasion; I gave the first parts to Sub-Inspector Rogers, and the second to Constable Coghlan; they were sealed up in a jar; on opening the belly the peritoneum was healthy, but the mesentery was red; the inspection of the body gave me no additional evidence, but my object was rather to remove the contents to have them analyzed; there was a dull slaty appearance in the stomach, the consequence of inflammation; the longer the person lives the less appearances of the poison after death. *To Baron Pennefather*—I consider the man to have died from weakness, the corrosive sublimate interfering with the digestive organs, and also from hemorrhage. *Cross-examined*—Cholera and dysentery were very prevalent through the country at the time; he was a stout, strong, well-built man, not likely to be affected by dysentery; I attended him for the mercurial salivation; the first effects of corrosive sublimate when given in large quantities are to produce a burning taste in the mouth, and vomiting; the deceased described as accurately as any medical man the effects which would follow the taking of this poison, and I was confirmed in my belief of what he had taken by finding an ignorant man describing day by day with the utmost accuracy what symptoms should follow the administration of corrosive sublimate; all the appearances could not have followed from the administration of bad whiskey, in which there was inserted bluestone and verdigris; the sublimate is very soluble; it is soluble in thrice its weight of spirit, and would leave no sediment if pure; verdigris has no mercury in it; three grains of sublimate have been known to cause

death, but a drachm will kill several, and eight drachms may be dissolved in one glass of whiskey; one may take as much of the poison and escape from death that would kill three others; some are more susceptible than others of the influence of poison. *To Baron Pennefather*—If the sublimate was in powder still I would not expect it to have been so dissolved in ten minutes that the man would not see some appearances in the whiskey.

The information of Simon Power was then read, in which the deceased swore that he got the whiskey from the prisoner: that the whiskey was rough in his mouth, and had a shocking stinking smell.

Inspector Rogers and Constable Coghlan proved delivering the contents of the stomach, &c. to Dr. Geoghegan.

Dr. Geoghegan, Fellow and Profr. R. O. Surgeons, Ireland, examined by Mr. Sauss—The medical history of the present case, as given in evidence, unequivocally establishes that the death of deceased resulted from poisoning by a soluble salt of mercury, and, by inference, that the compound taken was corrosive sublimate; the *non-detection of poison* in the various organs of deceased is not alone compatible with the fact of death from that cause, but in conformity with the laws which govern the elimination of poisons from the body. In the present instance the illness was of fifteen days' duration, a period quite sufficient for the escape of the offending matter by the organs of secretion, particularly the kidneys and salivary glands. Witness did not expect to discover mercury in the alimentary canal, but thought that traces might possibly be found in the organs which had appropriated it subsequently to absorption; the salivation produced by the soluble salts of mercury may be of a two-fold character, arising either from their local influence on the mouth in the act of being swallowed, or from their absorption into the economy; the former is a spurious salivation, which may be immediate, and is occasionally accompanied by factor of the breath; the latter is the true mercurial influence, which is usually manifested after the lapse of a couple of days. *Cross-examined* by Mr. Harris—Corrosive sublimate is incapable of communicating any peculiar or fetid odour to whiskey; a wine-glass full of the latter fluid may in the course of a few minutes dissolve as much of the poison as would suffice to destroy life: on this point only, witness is unable to concur in the very intelligent evidence of Dr. Boyd. *To Mr. Harris*—I did not make any experiment on that point to reduce my opinion to a certainty.

Mr. Harris addressed the jury, and submitted that there was not such a case as

would warrant the jury in arriving at the conclusion that the prisoner was guilty of the offence with which he stood charged. Counsel adverted in detail to the evidence, and to the doubts which must arise as to the cause of death.

Mary Walsh, and another sister of the prisoner, and two men in the prisoner's employment, were examined in detail, and their evidence was to the effect that the whiskey was given freely to the deceased and Murphy at the same instant, and that they did not leave the house for some time afterwards. The two men, Dwyer and another, also swore that the deceased vomited the day before he got the whiskey, and was on the ground for days after taking the whiskey. On cross-examination their evidence varied in many particulars.

Mr. Phayre, an apothecary, deposed to having made experiments as to the solubility of corrosive sublimate; and his evidence went to show that it could not dissolve in ten minutes, or for a period much longer; but on cross-examination, said that in a few minutes the whiskey might take up a large quantity.

Mr. Scott wished to examine Dr. Geoghegan who had, since being on the table, made an experiment at the request of the Counsel for the Crown.

Mr. Harris objected, but this being part of the Crown's original case, Baron Pennefather concurred in it.

Baron Pennefather charged the jury, who returned a verdict of Guilty.

Baron Pennefather was about to pass sentence, but after consideration directed that the prisoner should be removed and brought up next morning, (Friday).

The trial was one of a very interesting nature as to its medical details, and the learned Judge in the course of his charge, after complimenting the Counsel for the manner in which they discharged their duties, also adverted in high terms of commendation to the clearness and ability with which Dr. Geoghegan, of Dublin, and Dr. Boyd, of New Ross, gave their testimony as to the cause of death.

* * One question of especial interest in this case was, whether a tea-cupful of whiskey, poured on corrosive sublimate, would in *ten minutes* dissolve as much as would suffice to destroy life. Admitting the corrosive sublimate to have been in powder, the act of pouring would so agitate this as undoubtedly to cause the whiskey to take up a fatal dose; and if in lumps, the lumps would have been seen and have excited the suspicion of the deceased. Mr. Phayre, an apothecary who appeared for the prisoner, swore in his examination in chief, that the poison could not be dissolved by

the whiskey in ten minutes, or even in a longer period; and although he professed that this very decided opinion was based on experiments, he did not hesitate to swear in his cross-examination that in a few minutes the whiskey might take up a large quantity! But for this open recantation, the fairness of Mr. Phayre's opinion might have been readily tested by Counsel requesting him to drink some whiskey which had been poured on powdered corrosive sublimate and allowed to remain ten minutes!

It appears to have been a refined piece of cunning on the part of the prisoner to give the whiskey about the same time to two persons, but to take care that the cup should be only fully poisoned to one. This, with the non-detection of mercury in the body, might have overthrown the case, but for the convincing and judicious evidence of Dr. Geoghegan and Mr. Boyd.

Correspondence.

RELATIVE FREQUENCY OF THE PULSE AT DIFFERENT ELEVATIONS, AND AT DIFFERENT PERIODS OF THE DAY.

SIR,—If not trespassing too much on your columns, might I ask you kindly to permit me to make a few remarks on Dr. Bellingham's lecture, published in your columns of the 1st of March, with respect to the relative frequency of the pulse at different elevations and at different periods of the day. My opportunities have been pretty extensive, and my attention particularly directed to the pulse for the last 15 years at least.

1st. The pulse of a soldier in health, before breakfast, say 7 A.M. (in Hospital), in the recumbent posture, and free from nervous excitement, may be reckoned, according to my experience, at 60 or 64, and in the evening a few beats more, the difference depending upon the degree of debility. It is least frequent in the morning, however, when first convalescent from remitting fever; 54, or even lower, is then by no means uncommon. No doubt, as you have said, numerous exceptions will occur, depending chiefly upon collateral circumstances, as before or after breakfast, before or after dinner, fresh or fatigued, after a restless night or refreshing sleep; or it may be only these that make the difference; for if hungry, or fatigued, with the skin soft and perspiring, it is certainly lower in the evening.

2. I have never noticed the least difference of the pulse from elevation, whether

at Madras or Bombay, on the level of the sea: Poona and Belgaum, 2000 feet above it: Candahar 4000: Kelat or Cabul, 6000; or Ghuznee, or along the range of the Suliman Mountains, 8000 or 9000. Along the latter too, we several times changed our elevation from 1,000 to 2,000 feet in a day; so I cannot but think that the presumed difference has been originally based upon theory, and continued from generation to generation without further inquiry.

Very truly yours,
B. H. A. HUNTER,
Staff Surgeon.

We are all too apt to fancy, perhaps, that nothing is worthy of publication except it be extraordinary, or at all events something out of the way, and so it has occurred to me to test this, by throwing together a few common-place practical remarks, just as they present themselves, though if approved of we may extend them over all the more ordinary fatal diseases of the East and West Indies. The value of such remarks, however, being in some degree proportionate to the opportunities enjoyed, it will be necessary to premise with the usual "*experientia haud non paucorum annorum*," or, as that might be deemed too indefinite in the present instance, with a simple detail of the facts.

Our personal experience may be pretty nearly summed up in 28 years' service as an Army Medical Officer, (regimental chiefly*) in a variety of climates and localities; in Ceylon, to wit, 1½ years, Madras 1 year, Doab and Deccan 5 years, Bombay and Colaba 3½ years, Ghuzerat or Marwar 2 years, Scinde and Afghanistan, from the mouth of the Indus to Cabul, 1½ years, in the West Indies, (Barbadoes and St. Vincent), 1½ years; about three years at sea, mostly with troops, and the remainder in England.

We shall commence with cholera, for this was the most ordinary fatal disease during a great part of the period embraced, and of this we may say, cholera has in our experience been decidedly contagious, that it is not communicated by contact, as some would ingeniously limit the term, but by some subtle self-multiplying principle, like that of scarlet fever, typhus, or plague, though, if pressed for the proof, we could adduce abundance either ways. We could trace repeatedly its introduction and subsequent progress from individual to individual, and from place to place; or shew, on the other hand, that ourselves as

* One advantage a regimental medical officer possesses, is that if his patients are only scratched, they return again and again upon him till they die, or are invalided incurable.

well as many others have been in the midst of it for days, and have even, in the height of our zeal, sat by the bedside watching every movement or change in the temperature and pulse, almost from its commencement till its termination in death, without ever being affected with either cholera, colic, or diarrhoea. Nay, further, we might leave the domain of legitimate induction, and, mounted upon the wings of imagination, penetrate the dark portentous cloud, and there exhibit the cause of cholera in myriads of insects, like a dense flight of locusts darkening the air, hanging over the camp, or pursuing the tract of some devoted column. We might point to it amid the flowing Stercoraceæ, or exhibit it in the uredo fungi; or give it an aerial form, and trace its deadly course in the blast of the simoon. In short, could we collect a little of the marvels of its most marvellous origin and progress on various occasions, Ceylon* might stand abashed, whilst "Joe Miller"† we proclaimed *yet a man of straw*, and burnt him in the fire.

But, be the cause of cholera what it may, or its mode of propagation, nothing in our experience has so certainly predisposed to it as diarrhoea and dysentery; so much so, indeed, that on one occasion we lost every one of the class in Hospital at the period of its introduction, whether recently admitted or convalescent, in the short space of 36 hours, (of these, no less than 4 or 5 went off with the first funeral party, within twenty-four hours); and on another occasion, in the same regiment, meeting a detachment of 50 sick and wounded returning, it cut off 16 of the 19 with "chronic bowel complaint," in three days. Diarrhoea and colic too, that is, vomiting and purging without cramps or collapse, we have frequently noticed precede and also accompany cholera, and have even by the character of these been enabled to predict confidently its approach. Nevertheless, we have seen hundreds at a time, not less than one third of the regiment, suffering from serous diarrhoea, (both officers and men) several of them in a most violent degree, and yet not a case of cholera, nor yet a death in the corps from any disease even for months. I more especially allude to Tatta, on the Indus, in January, 1839, but more or less throughout Scinde and Afghanistan. It is true we were then ahead of the

cholera,—that is, where cholera had never been,—for hitherto the sword of the Beloochi and knife of the Affghan had to that proved an impenetrable barrier. No sooner were these removed, however, than it followed up in the rear, and the same year, as far as Kwetiah above the Bolan, was extremely destructive, as it was some years subsequently at Caubul, causing the city for some time to be almost deserted.* It was no doubt these interminable deserts, with their thinly scattered ferocious inhabitants, that so long kept the cholera within the bounds of the Indus; and even when it did get to Persia it was only by outflanking these, taking the sea route direct from Bombay. It certainly did not pass through Afghanistan or Beloochistan.

It has been too hastily inferred, we think, on various occasions, during the prevalence of this epidemic, that where diarrhoea has been checked or cured, cholera has been prevented. Not one in ten, perhaps, of such cases would ever have terminated in cholera, whilst, on the other hand, we have seen cases repeatedly on the line of march, from their first falling out of the ranks, with a sense of faintness, squeamishness, diarrhoea or vomiting, which in spite of every remedy have run rapidly into collapse, and proved fatal almost before the day's march was completed. The same malignancy we have noticed in quarters, and have often puzzled ourselves for some new method of treatment, even while the temperature was still good and the pulse tolerable; for we fancy there is an expression and gait indicative of mortal disease from the beginning. Indeed, it would not be difficult to show, statistically, at least, that cholera has a certain ratio of mortality whatever be the treatment, and whether this be in the East Indies, in England, or America. The West Indies, at least the British portion, it has not yet reached, though there is reason to believe, (from an examination of the records on the spot) that sometimes the first cases on an outbreak of yellow fever have been "returned" as such.

Treatment.—On this we have nothing new to offer. We may say, however, we have tried with and without venesection again and again, and certainly do think, if it can be practised with moderate effect, that it affords a much better chance of reaction, even though vomiting be induced, and the pulse sink for a time. Next to that in importance, we reckon Calomel gr. xx. c. Opii, gr. ij., notwithstanding the same

* "Ceylon," proverbial in the Army for its marvels.

† "Man of Straw."—Dr. Kennedy, in the introduction to his "Campaign in Afghanistan," says Joe Miller is no "man of straw," as he once was led to suppose, for he saw the veritable gentleman himself at the Cape of Good Hope.

* This is the usual way with the Natives of the East on any severe outbreak, and seems to be the natural way of dissipating the contagion. It is well to keep this in view.

has in this country been declared inefficacious, or in the more delicate Pil. Hyd. gr. x. c. Opil, gr. j. repeating the one or other once, twice, or oftener, till the vomiting and purging be allayed, and afterwards in smaller doses alternately with some such mixture as the following:—Mist. Camphor. Liq. Ammon. Acet. ss. ʒij.; Spirit. Ether. Nitrici ʒss.; next a strong blister to the epigastrium, so that, if possible, it may be coming into play about the time reaction is most likely to commence. For this the mustard poultice is too evanescent, and lastly stimulants. Of these we have tried a great variety, scarcely missing a new suggestion, but have found none in military practice superior to cold brandy and water. Frictions relieve the cramps of the calves of the legs, but, where these are abdominal, (as we observed in the English cholera of August, 1826) venesection, with the warm bath, and the large doses of calomel* and opium, already mentioned, are best. In such cases we augur less danger. In the Asiatic variety they more usually occur when the epidemic is about to subside. There is yet another variety of cholera, which we might call spurious, constantly occurring in regiments in the East Indies. It appears to be caused by poisoning, supposed often to be from stale sausages or pork, which have been kept in copper vessels, hawked about clandestinely by the natives. We have also seen it occasioned by arsenic, or something so very like cholera, where cholera is so common, that it was never suspected even, till the arsenic was found in the stomach. The former, however, are very seldom fatal.

We have said nothing of secondary fever, because we do not look upon that as essential. It seems rather to depend upon the protracted local congestions, or inability of the system to restore the circulation in these parts. It is less frequent in the east, where the course of the disease is more rapid than in England.

Prophylaxis.—As this paper is meant to be strictly practical, it will only be necessary here to notice such precautionary measures as we have ourselves known adopted, and the results. In August, 1833, cholera broke out in the hospital of the wing of the 2d, or Queen's Royal Regiment, in the town barracks of Bombay. The men were much crowded at the time, and with only a temporary hospital, separated off from one extremity of the rooms by a partition of straw matting eight or

ten feet high. The first affected was a native "ward-boy," who had been out in the native town. This was in the forenoon. At 5 P.M. the first of the patients in hospital was seized; and whilst I was with this patient, about 7 or 8 P.M., two others in the same ward; and, by midnight, one or two more. At daylight 16 palanquins were engaged conveying away the other sick to the Regimental Hospital on the island of Colaba, about two miles distant. Next morning those sufficiently recovered, were sent off in a similar manner, and again that evening and following day, to the General European Hospital in the Fort, which was near at hand. By the second evening there was a marked change in the character of the disease, and by the 5th it had altogether subsided. Its progress was from the extreme of collapse, almost without cramps, to strong spasms of the legs and abdomen. In all there were 54 cases of cholera, and about an equal number of choleraic diarrhoea and colic; and, of the 54, 8 or 10 proved fatal. These were nearly all of the first cases. The regiment lost in all 29 by cholera that year, besides women and children; but it was three times epidemic—to wit, in May, in August, and in December.

Again, in September 1842, cholera, which for months previously had been approaching from the southward, and from village to village, with immense mortality, reached Deesa on the border of Marwar, where the 2d or Queen's Royal were then stationed. We had scarcely heard that a village fourteen miles on the Ahmedabad road was deserted, than one morning at four o'clock, a child, already in the stage of collapse, was brought to the hospital by its mother. The latter appeared to be in good health; but, fearing the effects of her assiduity, I desired her to lay it on the bed. At 9 A.M. she too was seized; and in the evening both mother and child were laid in the same grave. Next morning another child was brought at 4 A.M., in the stage of collapse, by its mother. The same thing was repeated in every respect, and again in the evening both were laid in the same grave. The disease was found to be in the regimental bazaar, where the married women particularly went for their daily supplies. The bazaar guard was immediately withdrawn, and placed in a tent between that and the barracks, and all direct communication cut off; whilst the people of the bazaar were set to turn that almost literally inside out. The disease continued to prevail for some time in the married men's lines, called the Patcherry, but particularly in the hospitals, both male and female (these were in the same enclosure, and only a few paces apart); but

* The large doses of calomel there is reason to believe act as a local application, but the blue pill and opium are very effectual, particularly in diarrhoea. A stock was always kept ready on the lie of march.

not a case was admitted from the barrack-rooms or pendalls, though these extended from within 100 yards of the bazaar to within 50 of the patchery. The apothecary, who resided within the hospital enclosure, died, and 10 men, besides women and children: but this was a very deadly cholera,—scarcely any recovered; and even two men and one woman, supposed to have been out of all danger for a day or two, relapsed, or rather, we might say, had a fresh attack, and died.

Again, in April 1840, in H.M.'s 17th Regiment, of which I was then in temporary medical charge, we had lost two men by cholera (sporadic cases) on the island of Colaba, Bombay, and three by *coup de soleil* on the 29th,—the day we crossed over to Panwell with the right wing, *en route* to Poona. At Panwell we halted three days, waiting for carriage from Bombay; but there was no report of cholera in the neighbourhood—(it was, however, in Bombay). At the end of the second march,—for we made a long march from Choke to Khandalla,—we met with a native regiment coming in, having this disease among them; and, in consequence, we went a mile further. Here we had a few mild cases, and one died, I think. Next day we encamped between their two former encampments half-way, and had none; but the next day at Waugaum, on the same ground. There was some hesitation about this; but there was no other place at all convenient, and the native regiment had been quite free when here. The same evening cholera broke out with all its usual virulence, and turned the rest of our route towards Poona more like an orderly retreat, with the wounded perpetually crying "Water, water!" It was proposed by the officer commanding to make a push for Poona, but I dissuaded him from this, and so we continued our ordinary rate and distances, using only the extra precaution of keeping the walls of the tents open. Several were carried into hospital at Poona with secondary fever of a bad type, but there were no fresh cases after the first march. In all, ten men died on this occasion, but no officers, women, or children. A similar course was pursued on this march with the 2d, or Queen's Royal, in December 1833, and with a similar result; and also by the main body of the Bombay column of the army of the Indus, on their return, crossing the desert between Baug and Shikarpoor. But a more decided step was taken with the left wing of H.M. 57th Regiment at Arcott, near Madras, in 1845. Here they left the cantonment, and kept circling round in short marches, at the distance of ten or twelve miles: 29 men died, but I believe there were no fresh cases after they

left the cantonment. The same object may be attained nearly by a more ready method (the same as we adopted at Kalat when crowded with wounded, and the position, in a military point of view, did not admit of alteration)—to wit, by pitching the tents one day a few paces to the rear, another to the front or side, and again upon the old ground alternately.

Bristol, June 28, 1830.

ON THE COLORATION OF WATER BY ALGÆ.
—CAUSE OF THE COLOUR OF THE RED SEA.

SIR,—I beg to be permitted to offer a few observations on the subject of the coloration of the water of the Red Sea, of which, in the last number of the *MEDICAL GAZETTE*, you expressed a doubt.

The coloration of the Red Sea is neither a constant nor a general phenomenon, but, like that of the Serpentine, periodical and partial. It is therefore not surprising that some travellers on visiting that sea should report that its waters are not, as has been supposed, of a red colour.

Nevertheless, the fact of the coloration of the water of the Red Sea rests upon authority which would appear to be conclusive—viz., the testimony of several observers, and amongst the number Ehrenberg, who was the first to notice the phenomenon, and in honour of whom the plant occasioning it has been named by the celebrated cryptogamic botanist, Dr. Montagne, *Trichodesmium Ehrenbergii*.

In my History of the Fresh-water Algae a long account is given of the coloration of water by means of algae, from which I extract the accompanying particulars in reference to the Red Sea, and which may possibly prove interesting to some of your readers.

I have the honour to remain,

Your obedient servant,

ARTHUR HILL HASSALL.

66, Park Street, Grosvenor Square,
July 15th, 1830.

"During the year 1823 (writes Dr. Ehrenberg) I made a stay of many months at Tor, upon the borders of the Red Sea, close to Mount Sinai. On the 10th of December I there saw the surprising phenomenon of the blood-red coloration of all the bay which forms the port of that city. The high sea, without the boundary of the coast, preserves its ordinary colour. The short waves of a tranquil sea bring upon the banks during the heat of the day amucilaginous matter of a blood-red colour, and deposit it upon the sand in such a manner as that, in the course of a good half-hour, all the bay with the reed-

ing tide is surrounded with a red border of many feet in depth. I removed from the water some specimens with glasses (?), carried them to a tent which I had near the sea. It was easy to perceive that the coloration was due to little tufts, scarcely visible, often greenish, and sometimes of an intense green, but for the most part of a deep red. The water upon which they floated was always colourless. This very interesting phenomenon, sufficient to afford a reason for the etymology of the name which this sea has received (an etymology up to the present time always buried in complete obscurity) attracted all my attention; and I examined it at leisure, with all the care of which I was capable.

"The phenomenon of the Red Sea was not permanent, but periodical. I observed it three other times—the 25th and 30th of December, 1823, and the 5th of January, 1824."

The same phenomenon of the coloration of the Red Sea occurred at a later period, and on a scale infinitely more extensive, to M. E. Dupont, a distinguished advocate of the Isle of Mauritius. The following is the very circumstantial and satisfactory account of that gentleman, as contained in a letter addressed to his friend M. Isidore Geoffroy Saint Hilaire:—

MY DEAR FRIEND,—You demand of me certain details in reference to the circumstances in which I gathered the *cryptogamic* plant which I sent you from the Red Sea, and which you told me appeared a new species. They are as follow:—

"The 8th of July last (1843) I entered into the Red Sea, by the Strait of Babel-mandel, upon the steam-boat the *Atalanta*, belonging to the Indian Company. I demanded of the captain and the officers, who for a long time navigated in these latitudes, what was the origin of this ancient name of the Red Sea,—if it was owing, as some have pretended, to sands of that colour, or, according to others, to rocks. None of these gentlemen could reply to me; they never, they said, remarked anything to justify this denomination. I observed then for myself, as we advanced, whether the ship approached by turns the Arabian coast or the African coast, the red was in no part apparent; the horrid mountainous barriers which border the two banks were uniformly of a blackish-brown, except where in some places the appearance of an extinct volcano had left long white streams. The sands were white; the reefs of coral were white also; the sea of the most beautiful cerulean blue. I had given up the hope of discovering my etymology.

"On the 15th of July, the burning sun of Arabia awoke me suddenly by shining all

at once from the horizon without spot, and in all its splendour. I turned myself mechanically towards the window of the poop, to seek a remnant of the fresh air of the night before the ardour of the day had devoured it. What was my surprise to behold the sea tinted with red as far as the eye could reach! Behind the ship, and on all sides, I saw the same phenomenon.

"I interrogated the officers anew. The doctor pretended that he had already observed this fact, which was, according to him, produced by the fry of fish floating on the surface; the others said that they did not recollect having seen it before. All seemed surprised that I should attach such interest to it.

"If it be necessary to describe the appearance of the sea, I should say that its surface was covered with a compact stratum of but little thickness, but of a fine texture, of a brick-red, slightly tinged with rouge: sawdust of this colour, of mahogany, for example, would produce very nearly the same effect. It seemed to me, and I said at the time that it was, a marine plant. No one seemed of my opinion; so, with a pail tied at the end of a rope, I was able to procure a certain quantity of the substance. This, with a spoon, I introduced into a white glass bottle, thinking that it would be the better preserved. The next day the substance had become of a deep violet, and the water had taken a pretty pink tinge. Fearing that the immersion would hasten the decomposition, instead of preventing it, I emptied the contents of the bottle upon a piece of cotton (the same which I remitted to you). The water passed through it, and the substance adhered to the tissue. In drying it became green, as you actually saw it. I ought to add, that on the 15th of July we were by the side of the town of Cosseir; that the sea was red the whole day; that the next, the 16th, it was the same, until near mid-day, the hour at which we found ourselves before Tor, a little Arabian village, the palms of which we perceived in an oasis on the border of the sea, below the chain of mountains which descends from Sinai, even to the sandy shore. A little after mid-day, the 16th, the red disappeared, and the surface of the sea became blue, as before. The 17th we cast anchor at Suez. The red had consequently shown itself from the 15th of July, towards five o'clock in the morning, up to the 16th, nearly an hour after mid-day,—that is to say, during thirty-two hours. During this interval, the steam-boat, making eight knots an hour, had traversed a space of 256 miles, or 85 leagues and a third.

"In the different works relative to Egypt and the Red Sea which I have had occasion

to read, I do not recollect to have found mention made of a similar fact. It appears to me, nevertheless, but little probable that it has not been observed by others. I reproached myself for not having questioned the Arabian pilot whom we had on board, and who for twenty years had traversed that sea. This idea unhappily presented itself too late.

► "If it should be in your opinion worth the pains, I would demand new observations of the surgeon or officers of the *Atalanta*, for it would be easy for me to write to them by way of Alexandria.—Believe me,

"My dear Geoffroy, &c.

"EVENON DUPONT."

FAT AND UGLY ANIMALCULA IN LONDON WATER.

THE recently published Report of the General Board of Health on the supply of water to the metropolis contains a curious piece of evidence by a Dr. Angus Smith, from which we learn, for the first time, that the bodily condition of animalcula forms an item in estimating the quality of the Thames water. It appears that specimens taken at Hungerford Market, and on the London side between Blackfriars and Southwark Bridges, "contained animalcules larger, fatter, and uglier than any preceding. One creature was observed about a thirtieth of an inch in size. When the deposit of mud was removed, and the water seemed clean, these specimens were allowed to stand some time. In a short time the flocculent matter spoken of was formed, brown like iron-rust, and the covering of one side of the vessel by the brown animalcules took place also on the side next the light."—*Report*, p. 41.

Unlike Dr. A. Smith, we are inclined to draw a favourable augury from the larger size and fatness of river animalcula. We say nothing of their personal beauty, for they have always appeared to us to be microscopic monstrosities. Large and fat animalcules must consume a larger portion of organic matter than the lean and consumptive-looking infusoria. They thus tend to depurate the water, and to render it more fit for the use of man. We have no evidence that living animalcula, fat or lean, are more unwholesome when swallowed in water than oysters, shrimps, or lobsters, and knowing the nutritious properties of the first-named mollusca, we decline to adopt the assumption that they are injurious to health.

In this report issued by the Board of Health, the term *animalcula* is invariably spelt *animalcules*!

TESTIMONIAL TO DR. CONOLLY.

A MEETING was held Saturday, August 3, at 12, Old Burlington Street, Lord Ashley in the chair, to take the necessary steps to present John Conolly, M.D., of Hanwell, with a public testimonial, commemorative of his invaluable and most successful labours in ameliorating the treatment of the insane; and a committee was appointed to carry the resolutions of the meeting into effect. It was resolved that the form of the testimonial should be a portrait, to be presented to Dr. Conolly's family, and an engraving from the same to be presented to the subscribers. The subscriptions are to be limited to five guineas; subscribers of two guineas and upwards are to be entitled to proof impressions of the engraving; and subscribers of one guinea to prints. Sir James Clark and Dr. Little were appointed treasurers, and Dr. Forbes and Mr. Frankum secretaries. It is not doubted that a very extensive list of subscriptions will be obtained, Dr. Conolly being one of the few men whose services in the cause of humanity have made a marked impression on society in his own day. Although not the originator or first advocate of the rational or non-restraint system of treating the insane, Dr. Conolly has been the great means of its introduction into general use, both in public and private asylums, by his strenuous advocacy of the system on all occasions, and by his own example at Hanwell. It is a fact that, since the first appointment of Dr. Conolly to the great asylum at Hanwell, now upwards of ten years, not a single patient (out of a thousand constantly there) has worn a strait waistcoat, or sustained any other form of restraint, except occasional seclusion for a brief space in the patient's own room. Such is at present the general treatment in most of our asylums, the mild and rational system being now almost the only one followed. A striking fact was mentioned at this meeting by Lord Ashley,—*vis.* that under this new system the proportion of suicides has decreased immensely; and all those who have been accustomed to see the insane are well aware that the very character of the disease, as it now shows itself in our asylums, has been extremely changed by the modern treatment. Dr. Conolly, as we have said, having been the great agent in bringing about this state of things, it is impossible to overrate the good he has done to his fellow creatures; and there can be no sort of doubt that the manner in which Dr. Conolly's professional brethren and the public at large will respond to the appeal of the committee, will prove how deeply the sense of his great services is impressed on the minds of his countrymen.—*Observer*.

A SPECIMEN OF MEDICAL EVIDENCE.

IN a case of manslaughter lately tried at the Bodmin Assizes, in which deceased died in a few minutes after having received two blows on the head with the fist, the surgeon is reported to have delivered himself of the following curious piece of evidence:—

"The surgeon said, he considered the deceased died from apoplexy, which might have been occasioned by the blow. He did not make a *post-mortem* examination, because the coroner's jury did not wish it. The witness, upon being pressed in cross-examination, went into all kinds of possibilities. The deceased might have been attacked with apoplexy, even without a blow. He was a stout subject, and therefore liable to apoplexy; and from the surgeon's evidence it would seem that, not having had a *post-mortem* examination, he could not tell much about it, and he could not say anything, in fact, that was of any value upon the subject."

On such evidence there could be no conviction for manslaughter. The prisoner, although he had undoubtedly caused death, could only be found guilty of a common assault.

THE BRITISH MEDICAL FUND.

AT a recent meeting of this Society, Dr. Forbes in the chair, it was stated, that subscriptions to the amount of £220. 8s. 9d., had already been received, which the committee thought was highly satisfactory, remembering that only a few weeks had elapsed since they were authorised to call for payments in respect of membership; and they had great pleasure in stating that the promises of support they had received, from all parts of the kingdom, had been most numerous, and the approval of the plan of the Society, by the profession, as far as they could learn, had been almost unanimous.

THE LONDON HOSPITAL.

THE Duke of Cambridge has become a Life Governor of this institution, and has consented to allow himself to be proposed for the office of President, at the next General Court of Governors.

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 2nd inst.:—Messrs. H. C. Warren—J. B. Allen—R. Leach—G. P. Rugg—M. Ingle—J. Hutchinson—T. Ball—E. S. Willett—T. P. Johnson—W. Draper—W. G. J. Ayre—M. C. Dukes—W. H. Walker—G. C. Attfield.

Admitted on the 6th inst.:—Messrs. E. Hunt—J. Chambers—J. N. Jakins—A. Thornton—W. W. Tinsley—J. H. Thomas—T. G. Fitzgerald—J. Rigby—T. Lancaster—T. Howell—J. Stephenson—Henry Nelson.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 25th July, 1850:—Charles Young, Lewes, Sussex—Henry William Bromley, Rippingale, Lincolnshire—John Hunt, Cirencester, Gloucester—Francis Salter, Wrexham, Denbigh—John Mathew Charlton, Durham—William Jackson, Bolton-le-Sands, Lancaster.

OBITUARY.

On the 22nd of May, at Rio de Janeiro, Christopher Fryer Curtis, Esq., M.D., in the 29th year of his age.

On the 28th ult., at Fareham, Hants, James Ainge, Esq., surgeon, aged 63.

On the 30th ult., at Aberystwith, in his 44th year, William Thompson, Esq., Surgeon, Kingston, Herefordshire, sincerely regretted and lamented.

On the 5th inst. at Cheltenham, James M'Cabe, M.D. aged 59. *R. I. P.*

Selections from Journals.

TREATMENT OF ANGINA PECTORIS.

DURING a paroxysm, after all evident exciting causes have been removed, the treatment will be active in proportion to the strength of the patient and the violence of the symptoms. If there is reason to suspect an effusion of blood into the medulla oblongata, active depletion would be indicated, as recommended by Parry and Burns, even in plethoric individuals, by venesection, leeches, or cupping over the spine. Whatever the supposed cause, opiates, antispasmodics, and carminatives, are usually given, with ether, ammonia, or other stimulants, if there be coldness and faintness. To these would be added counter-irritation by blisters, but especially by dry cupping over the spine. Besides these, and others, which would occur to every one, we would advise the inhalation of oxygen, as recommended by Dr. Robert Reid, in the *Dublin Transactions* for 1817. We have seen that the principal danger is from insufficient aëration of the blood; so that, by such inhalation, the immediate symptoms of suffocation might be relieved, and sufficient time gained for the removal of the exciting cause.

During the intervals, in addition to the numerous precautions and remedies detailed in the books, we would suggest the preventive and curative treatment of neuralgia and rheumatism, whenever these may seem to have any connection with the past history of the symptoms.

We think, however, that the great remedy must be *electricity*, which, according to Matteucci (quoted by Dr. W. F. Channing, *Medical Application of Electricity*, p. 10), differs from all other nervous stimulants in that it excites sensation at one time and contraction at another, according to the direction in which it traverses a nerve: which alone has the power of increasing or diminishing the excitability of a nerve, according to the direction in which it is made to flow; which has the power of awakening the excitability of a nerve, after all other stimulants have ceased to act. The form to be preferred depends on whether we wish merely to stimulate the filaments of the par vagum in the organs to which they are distributed, or to produce structural change in the medulla oblongata. In the former, electro-magnetism would be indicated; in the latter, the uninterrupted current of the battery. If electro-magnetism should fail in the first, the battery should be tried, as this has been found beneficial in paralysis without structural change, where the first has failed. Without careful diagnosis, therefore, harm instead of good might ensue. By stimulating the paralysed spinal accessory, not only is the vitiated air expelled from the lungs, but oxygen is admitted, which might also be increased by inhalation of this gas; so that these two remedies might be advantageously combined. A current in the direction of the nervous ramifications would stimulate directly the motor filaments; in the opposite direction, the sensitive filaments: but in the mingled filaments of the par vagum, reflex action will often cause similar effects, in whichever direction the current is passed. However, in cases of spinal irritation or inflammation, it would be improper to send a current towards the medulla.—*Dr. Kneeland, in American Journal of Medical Sciences.*

CHEMICAL ANALYSIS OF CHOLERA EVACUATIONS.

M. MIALHE has established, with M. Andral, that these contain neither albumen nor fibrin; but, on the other hand, that choleraic liquids yield an abundant precipitate with various chemical reagents, this precipitate being of an albuminous nature, the product of final digestion of albuminous aliment.

M. Masselet, from his experiments, observes—The presence of albumen depends upon the character of the evacuations in cholera; the rice-water stools do not contain albumen, but it may be found in considerable quantities (as much as four or five per cent.) in the yellowish viscid motions streaked with blood, and which deposit portions of epithelium and pus globules.

M. Masselet has also made the observation, that from the same patient the evacuations during life may yield but mere traces of albumen, while after death albumen may be found more copiously in the contents of the intestines. He also noticed, that the stools passed at the later period of the disease contain more albumen than the earlier evacuations.—*L'Union Médicale.* x

TRAUMATIC TETANUS CURED BY FRICTIONS WITH TINCTURE OF BELLADONNA.

M. BRESSE, surgeon at the Military Hospital of Rennes, proposed, in 1848, the treatment of traumatic tetanus by the application of tincture of belladonna, and reported a case, in which it had been successfully employed, in the *Gazette Médicale de Paris* of Sept. 30, 1848. M. Bresse has now placed on record another case which has come under his notice. The patient, one of the *Garde Mobile*, received a wound on the 20th of March; tetanic symptoms appeared on the 5th of April. Frictions of belladonna were commenced on the 6th, and by the 12th the patient was out of danger. Imprudently exposing himself to cold, the tetanic symptoms returned in the muscles of the back, but were quickly removed by again having recourse to the frictions.

The tincture employed was composed of five parts of extract to eleven of alcohol, and was applied all over the body, and more particularly over the rigid parts.

M. Bresse adds, that another practitioner has arrested trismus, which he feared would proceed to general tetanus, by the same means.—*Gazette Médicale.* x

ON THE ACTION OF STRYCHNIA IN CHOREA.

MM. TROUSSEAU and LASSGUE have been led to regard chorea as a partial paralysis; and they have found strychnia of great service in the treatment of this disease.

The form in which they have administered this preparation is that of the sulphate, which they have preferred, on account of its solubility. Their mode of exhibition of the salt has been by the solution of five centigrammes, = 77 English grains of the sulphate, in one hundred grammes, = 1500 English grains, of simple syrup. The dose for infants, of from six to twelve months old, has been 30 grammes, = 45 English grains of the syrup, every six hours; for children fifty grammes, = 75 English grains, and for adults sixty grammes, = 90 English grains. It may be observed that seventy grammes, = 108 English grains of syrup contain one centigramme, = 154 English grains, of the salt of strychnia.

The beneficial effects are seen in proportion as muscular rigidity occurs. If spasm occurs the dose requires to be diminished.

The dose in any case is to be very slowly and cautiously increased. When the cure appears to be effected it is still advised to continue the use of the remedy for a time, decreasing the dose very gradually—*L'Union Médicale*.

BOOKS & PERIODICALS RECEIVED

FOR REVIEW,

DURING THE LAST TWO WEEKS.

The Principles of Surgery. By James Miller, F.R.S.E. 2d Edit. Edinburgh.

BIRTHS & DEATHS IN THE METROPOLIS

During the Week ending Saturday, Aug. 3.

BIRTHS.		DEATHS.	
Males.....	772	Males....	462
Females..	712	Females..	455
1484		917	

CAUSES OF DEATH.

ALL CAUSES	917
SPECIFIED CAUSES	917
1. Zymotic (or Epidemic, Endemic, Contagious) Diseases.....	277
Sporadic Diseases, viz.—	
1. Dropsy, Cancer, &c.	40
2. Brain, Spinal Marrow, Nerves, and Senses	99
4. Heart and Bloodvessels.....	38
5. Lungs and organs of Respiration	70
6. Stomach, Liver, &c.	61
7. Diseases of the Kidneys, &c.	10
8. Childbirth, Diseases of Uterus, &c.	7
9. Rheumatism, Diseases of Bones, Joints, &c.	11
10. Skin.....	3
11. Old Age	30
12. Sudden Deaths.....	2
13. Violence, Privation, Cold, &c....	26

The following is a selection of the numbers of Deaths from the most important special causes:

Small-pox.....	13	Convulsions.....	26
Measles.....	11	Bronchitis.....	22
Scarlatina.....	20	Pneumonia.....	28
Whooping-cough.....	18	Phthisis.....	123
Diarrhoea.....	136	Lungs.....	8
Cholera.....	11	Teething.....	7
Typhus.....	32	Stomach.....	6
Dropsy.....	17	Liver.....	13
Hydrocephalus.....	30	Childbirth.....	7
Apoplexy.....	17	Uterus.....	8
Paralysis.....	19		

REMARKS.—The total number of deaths was 103 below the average mortality of the 31st week of ten previous years. Of the 136 fatal cases of diarrhoea, 124 were among infants. Of the 11 cases of cholera, 6 were among infants. There is no appearance of the malignant cholera in the metropolis.

METEOROLOGICAL SUMMARY.

NOTICES TO CORRESPONDENTS.

Communications have been received from Mr. Galloway, Dr. W. Addison, Mr. Lonsdale, and Dr. Day.

Mr. J. H. Tucker.—The circular did not reach us, or it would have been inserted.

Mr. T. H. Johnston.—We can enter no further into the matter. We wished at the time to publish the names of all the parties concerned, but could not obtain permission. That the facts were as published, is beyond all doubt. We saw the powders, and satisfied ourselves of the correctness of the analysis.

Lectures.

LECTURES

ON THE

MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.

Lecturer on Medical Jurisprudence in the
University.

LECTURE II.

Medico-legal authority in insanity—Civil consequences of the state—Legal subdivisions; idiocy, lunacy, unsoundness of mind.—Legal doctrines.—Medical Classification; (a) general insanity; 1 amentia, 2 mania, 3 dementia; (b) partial insanity; 1 monomania, 2 moral insanity relation of the foregoing states to each other; doubtful and variable cases—General description of the insane state: the relation of country, age, sex, station, temperament, and social condition, to disease of the mind; (a) moral condition of lunatics—Premonitory moral disorder—The emotional features of insanity, selfishness, &c.

THE members of the medical profession have very important duties laid upon them in the detection and discrimination of insanity. They are certainly not more peculiarly qualified than any other equally intelligent class in the community to determine upon the evidence of mental inefficiency, or to come to sound conclusions on the important question of civil competency, and the more difficult subject of criminal responsibility; and, on this ground, their authority in cases of mental unsoundness has sometimes been querulously objected to, and their judgment undervalued. Leaving it to jurymen and judges to solve these questions authoritatively and judicially, there is no class better entitled, by education and general acquirements, to undertake the investigation of mental conditions, and none so well qualified to pronounce upon the point of mental health. It would, however, be to the interest of the public, and the credit of the order, that these particular medico-legal functions were discharged by the specially experienced section of the profession. The medical examiner alone has aids in his knowledge to guide him to a correct opinion as to the healthy or unhealthy state of mental organs, and the soundness or unsoundness of the functions

of the brain. He has had practice opportunities of learning how to distinguish mental from delirious, lethargic, hysterical, and other allied conditions, and can discover evidence by detecting symptoms which others would overlook, and appreciating indications which the non-professional would misconstrue. The physician is a jurist in cases of insanity, not on psychological, but pathological merits. He knows the phenomena of mental aberrations, and, with no greater metaphysical acumen than his neighbours, is better able to distinguish the results of disease. Insanity is the phenomenon of ignorance or vice as the effect of disease.

Insanity, when substantiated, annuls agreements entered into in that condition, deeds executed, and testimony given; and it is the duty of the medical jurist to examine persons suspected to be labouring under diseased mind, and to give evidence fitted to guide juries to a right decision on the question of the competency or responsibility of such individuals. He has to investigate the foundation for the pleading of insanity, when urged in criminal cases as a reason against trial, judgment, or punishment; and to testify as to the mental condition of parties whose wills, contracts, marriages, declarations, or confessions, are attempted to be set aside upon the same plea. It is upon the written certificates of medical practitioners that a legal warrant is obtained for the confinement of a person as lunatic in any hospital or asylum, by which his personal liberty is infringed, and, it may be, his civil privileges curtailed, and his responsibility to the law for a time suspended. After an individual has been so far recognized as insane, it is necessary, before curators or others can intrude with, or administer his estate, that his incapacity be shown to the satisfaction of a jury, as in a court of commission in lunacy, which is the mode in England, or in the Sheriff's court, which is the plan followed in Scotland. Medical testimony is a necessary preliminary to such proceedings, and in their course the professional evidence is the most important.

Before we turn our attention to the forms and varieties of mental derangement recognized by medical writers who have studied the subject, let me first introduce you to the divisions and doctrines which the authority of the law has established.

Lawyers speak of three forms of insanity—idiocy, lunacy, and unsoundness of mind—and attach to these terms the following meanings: *idiocy* is congenital insanity, and therefore always defect of mind; but the deficiency of intellect must amount to an extreme of imbecility; *lunacy* is an acquired insanity, not of necessity permanent, but

capable of lucid intermission, or complete cure; and *unsoundness of mind* implies such a degree of mental disease, or decay, as renders the subject of it unfit for the management of his affairs.

All who are idiotic, lunatic, or unsound of mind, are looked upon as incompetent in civil cases; but only the first of these classes are of necessity irresponsible for criminal actions. Lunatics, and others of diseased mind, are accountable for any crime not committed during such a paroxysm of their disorder as may be held to have subverted the power of distinguishing right from wrong.

It will appear to you, then, that we have, in law, three classes of the insane, and, as it were, two degrees of insanity—the lower degree vitiating civil acts; the higher absolving also from criminal liability. Now, the species of evidence admissible for the establishment of the former, or lower degree, will not suffice to substantiate the latter. In respect to a civil contract, proof of incompetency may be derived from any circumstances indicative of diseased mind, even from the character of the act itself; but in regard to a criminal offence, the evidence of irresponsibility cannot be derived from the action, but must be deduced from such other circumstances as manifest the individual's incapacity to distinguish lawful from unlawful.

A civil act, flowing from an insane delusion, will, on that very score, be invalidated, and deprived of efficacy; indeed, the rule is, that the civil deeds of a lunatic are void, even when they are not the results of insanity, though to this principle there are recorded exceptions. But a lunatic who has compassed a criminal action is not of necessity absolved from legal consequences, even should the offence have been a natural result of his insane delusion.

Such is a brief statement of legal doctrines; and they have given rise to much and intemperate criticism. They are the results of an imperfect knowledge of the disease, with a clear estimate of its practical consequences. The divisions are not nosological, but judicial: you have not mania, melancholia, and so forth, but only incapacity to learn the law—incapacity for civil freedom—incapacity to obey the law—and incapacity for personal freedom—the exponents of a diseased state conventionally divided into idiocy and lunacy, and, in order that the classification may be perfectly comprehensive, supplemented by a vague condition, called *unsoundness of mind*. A greater anxiety seems manifested to guard the lunatic's pocket, and the interest of his heirs, than to protect his life. He shall not by his harmless folly place either himself or his friends at disadvantage,

but a criminal action shall not interfere with his privilege of being condemned. Harmless acts may be evidence of his lunacy, but illegal ones shall not; for it is assumed that he may be blind to what is merely foolish, and yet at the same time able to distinguish and avoid what is sinful. The law has a ready eye for insanity in a civil deed, but will not even look for it in one that is criminal. Freedom of will is held to be quite compatible with diseased judgment; and the mind which is enlaved by a delusion is still presumed to have the power of disobeying it. The plea of civil incompetency can be based upon any action of the diseased mind; but that of criminal incompetency must be laid on a more restricted foundation. Disqualifications for the rational management of affairs where it exists, is in general readily seen in the confusion which it has created, and is always possible of legal proof; but non-responsibility for crime is frequently first suspected, in consequence of the act for which the individual is called in question, and is held to require a species of evidence that cannot be put to a satisfactory test. Under legal expositions of such doctrines, lunatics may be carried from the asylum to the jail, and, almost idiots, swing on the gallows. Not only may such things be, but such things have been, and within recent memory. No degree of imbecility, unless a supreme degree, will annul guilt and avert punishment; for if there be any glimmering of reason, the imbecile is not an idiot in the legal acceptation, but capable of distinguishing good from evil, and thereby accountable to the law. The best evidence of insanity may be rejected in conformity with the above dicta, for doubtless, in some instances, the fullest proof of an insane mind at the time will lie in that inadmissible particular, the character of the crime itself. To adduce such testimony would be deemed equivalent to taking for granted that which it is an object of the trial to determine; but, if it is also an aim of the inquiry to come to a just decision, there are cases in which the aspect of the criminal circumstance must be permitted to have influence.

In medical opinion, insanity results from the action of certain pathological agents, so limiting the faculties of the mind as to render, in some matters, the influence of judgment unseen, and right conduct impracticable by independent personal effort. Incompetency in the affairs of life is one manifestation of the condition, loss of voluntary control another; but perhaps neither feature is a complete portrait of any one case. It is the accident of external circumstance that educes either characteristic the more prominently, and leads to the mistake of accepting a merely comparative

soundness of the other for perfect integrity. For full government of the conduct, all the faculties of the mind are required; and when it is clear that the judgment has suffered to the extent of producing civil incompetency, we must admit that one important guide of the will is enfeebled, and a presumption of irresponsibility already obtained. We, who have daily opportunities for knowing that no vital organ of the animal body suffers alone, may be prepared to give more than due weight to seeming indications of a corresponding analogy in the psychical economy; but when we consider how judgment hangs on memory, memory on attention, and attention on a power of will, we cannot but in the very fact of received delusion recognize a defect of the faculty which gives personality to our actions.

Those members of the legal profession whom official position has afforded opportunities of becoming acquainted with the nature of insanity, will in general be found to have formed views on the subject more in accordance with medical opinion than those which are ordinarily expressed by their brethren. Were those lawyers to whose duty it may fall to address juries in such cases, to devote a share of their attention to the study of mental disease, either by reading, attending lectures, or, best of all, by visiting the insane themselves, there would be less opportunity to remark a difference between medical and legal opinions.

The most generally recognized division of insanity is into general and partial.

General insanity is unsoundness of the whole mind,—the powers of intellect, emotion, and will, being all involved in a greater or less degree; so that the individual may neither think, feel, nor act, as an intelligent and responsible being in regard to any matters. Such a state may be the result of three different conditions of the mind, and its phenomena will vary with its origin. It may be the natural consequence of the *non-development* of mental faculties to the healthy human standard, in which case thought will be feeble, the expression of emotion imperfect, and conduct foolish. It may result, in a mind of natural capacity, from *disorder* of the mental faculties, occasioned by a loss of voluntary control over the succession of thoughts; and then, thinking will be delirium; language, incoherence; and action, extravagance. Lastly, general insanity may be the accidental consequence of *obliteration* of certain faculties by disease, in which case the phenomena will be a mixture of those of non-development and disorder. There are, accordingly, three distinct forms of general insanity; and to these the terms *amentia*, *mania*, and *dementia*, have been applied.

Amentia is congenital general defect of mind, intellectual, emotional, and impulsive. Under this term we comprehend idiocy, and all the degrees of natural imbecility that may be included in the general term insanity. In its highest degree the mental feebleness is found to be associated with imperfect physical development; and the whole phenomena are, by Feuchtersleben, referred to a depressed cerebral, spinal, and even ganglionic vitality.

Mania is that form of insanity characterized by general perversion of the ordinary mental powers of the individual, so that no aspect of his mind is natural. There is loss of voluntary control over thought, emotion, and action, manifested in delirium, extravagance, and motor excitement. Its phenomena have been referred to cerebro-spinal exaltation. *Mania* has been divided into acute, chronic, remittent, intermittent, epileptic, hysterical, and puerperal, according to certain features in its history. The phrase "moral mania," which you will sometimes meet with, does not imply any variety of mania, being employed to indicate, not a species of general, but of partial, insanity.

Dementia is general deficiency of mental power, intellectual, emotional, and impulsive; not congenital, but the consequence of disease or natural decay. It includes all forms of acquired imbecility, and has the features, but not the history, of *amentia*. Its symptoms are those of impaired voluntary control over thought, feeling, and action, manifested in incoherence of language, irrational excitement, and a tendency to spasmodic motions and paralysis—phenomena which may be referred to cerebro-spinal injury. It occurs as a primary form of insanity in persons of uncultivated or weak mind, but much more usually is a secondary disease, and the result of some other form of the disorder. On the table written up before you, you will find the terms acute, primary, chronic, secondary, and senile, employed to designate its varieties.

Partial insanity is a term which would evidently imply unsoundness of certain of the mental faculties, with a natural condition of the rest; and indeed you will find it so defined by most writers; but it is much nearer the truth to say that it is a more limited exhibition of unsoundness, or a less degree of the same state as general insanity. The mind is so far diseased, that there are one or more intellectual or emotional ideas with which it cannot deal as the minds of other men would do. The judgment is constantly at fault on some point, and the will unfree; but though the points are limited in number, the confusion which they occasion in the mind is great.

general, not partial. Partial differs from general insanity, rather in the number of manifested aberrations, than in the number of faculties involved. It also, I believe, may be the result of congenital defect, and accidental obliteration of faculties, as well as a mere manifestation of derangement of powers naturally complete. It may have the character of imbecility or defect, as well as that of confusion or delirium. Two kinds of partial insanity are recognized—viz., monomania and moral insanity, which I shall now briefly define.

Monomania is that form of insanity in which the judgment is evidently incapacitated on certain subjects, yet seems to be sufficiently capable of acting in regard to others. A fixed delusion fetters the attention, overruling the influence of all opposed perceptions, and directing the conduct. The phenomena of the state are referable to a persistent morbid cerebral action. Monomania has been subdivided into a multitude of forms, to which, as you see from the table, various pedantic designations have been applied, intended to be descriptive of the nature of the most prominent diseased manifestations. The best practical division would be, into monomania with depression, in which the delusions are productive of despondency; monomania with exaltation, in which they are such as to elevate the self-esteem of the individual; monomania with alternation, in which the morbid idea sometimes occasions excitement, sometimes depression; and monomania with indifference, in which the craze can neither be said to be of a high nor of a low cast, being of a kind that negatively affects self-estimation.

Moral insanity is that form of the disease which is manifested, not by incapacity of judgment and intellectual aberrations, but by morbid emotions, leading to loss of control and blind or irresistible obedience to disordered impulses. In all cases, though the intellectual power is below the average standard, it is the actions of the individual that are irrational, and not the words; there may be feebleness in thinking, but delirium only in the conduct. The phenomena might be accounted for in the supposition of a depressed cerebral vitality in combination with a state of cerebro-spinal irritation. The varieties of the disorder are many; and it is probable that some of them are congenital defects. I would distinguish two kinds of moral insanity—viz., diseased passion, and insane impulse. Of the former, erotomania and nostalgia may be taken as examples, and the latter would include the propensities to suicide, homicide, theft, incendiarism, drunkenness, and unnatural crimes, where such can be characterized as diseased. Feuchtersleben

seems to hold that insanity of impulse is just a variety of mania (*mania sine delirio*), in which obscure feelings in the nerves of vegetative life—the ganglionic system—acquire such an intensity as to infringe on the motor nervous sphere, and thereby occasion delirious involuntary action.

You will find mention in medical writers of such forms of insanity as fatuity, incoherence, melancholy, brutality, &c.: these are not additional varieties, but merely terms used in place of the foregoing, better employed to characterize symptoms than to construct a classification. There are just five leading forms of insanity—*amentia*, *mania*, *dementia*, *monomania*, and *moral insanity*; these form distinct natural groups, though neither absolutely separated nor harshly outlined. From what I stated to you of the relation of partial to general insanity, you will judge that cases of a composite order may be of occasional occurrence. The acquired forms, by which you are to understand all, with the exception of *amentia*, not unfrequently merge into each other; and instances from time to time appear, of a description so intermediate as to be with difficulty classified. There is sometimes an alternation of one form with another; a case of *monomania*, for example, assuming, during a casual paroxysm of excitement, the features of *mania* or *dementia*. The progress of the disease not unfrequently exhibits, in a single individual, every description of disordered mind. The patient is at first morally insane; then he adopts some particular delusion, and is evidently a *monomaniac*; delusions multiply, excitement supervenes, the mind acts sanely on no occasion, and his whole aspect is maniacal; finally, this violent cerebral disturbance produces irrecoverable mischief in the brain; the excitement abates, or assumes a chronic type, but the powers of the intellect are as much or more in abeyance than ever, and he falls into the state which is termed *dementia*—the natural termination of every state of disordered mind which resists the influence of remedies. In the most ordinary mode in which insanity is developed, moral disorder is the first indication of the disease. The patient labours under emotional perversion—is, as it were, morally insane before he manifests intellectual derangement; and the disease not unfrequently disappears by retracing the same steps. The patient has not completely recovered, however unencumbered the imagination and unfettered the judgment, so long as the affections, desires, and sentiments, have not regained their former character and tendencies. Until the cure is thus completed, though the individual should be reckoned sane enough to be competent to his own management, and be libe-

rated accordingly, no one who has had experience of lunatics will regard him as sound enough to be warranted and trusted. Such an one will either acquire additional mental firmness, or be certain to relapse into his former state of disorder, upon the slightest exciting cause, or without the influence of any apparent agency whatever. He will not remain stationary, an example of a man with a new moral character—a second edition, but not improved.

I shall not weary your attention with a separate description of each of the above forms of lunacy. I have already given you certain specific distinctions, and shall now portray the generic features of insanity,—the features which distinguish it from other conditions, and which will be most conveniently taken up, with certain other particulars that require notice, in a *general description of the insane state*.

Diseases of the mind are most common in highly civilized communities, and in countries which have acquired the highest degree of political and religious freedom.

They are also, upon the whole, more common in the female than in the male sex,—a fact which is thought, however, to be in some degree affected by station in society. In the higher ranks, according to some observations which have been made both in Britain and in France, lunacy prevails more among males than amongst females. The more sensitive character of the nervous system in females, and their less perfect mental and bodily training, would lead us to expect a great preponderance of them amongst the insane, as there no doubt would be, were it not that the greater prevalence of intemperance and vice amongst men serves to bring up the proportion on the other side nearly to an equality.

As to *age*: insanity is not a disease of early life, nor is it so liable to occur in declining years as when both mind and body are at maturity. The most common period of life for the appearance of insanity is between 30 and 40; rather earlier in the female than in the male sex. About three-fourths of all cases occur between the ages of 20 and 50. Below puberty, insanity is almost unknown, unless in the forms of congenital and accidental imbecility; by which last term I mean imbecility of mind, the consequence of convulsions, fever, or accidental injuries of the head.

The physical *temperament* which shows the greatest tendency to mental derangement is the nervous; the temperament which is least liable is the sanguine. As far as observation has led me to any conclusion on this point, I would say that the greater the admixture of the nervous and

the lymphatic temperaments, the greater is the tendency to madness.

All writers concur in representing the married state as more exempted from the danger of lunacy than the state of *celibacy* is,—a statement verified by numerical returns, and still farther strengthened when it is considered that the mean age at which insanity commences is reckoned at 34.* If, then, we were to imitate the phraseology of certain statisticians who speak of “the average man,” we should say that the average lunatic is a female about 35 years of age, and of a lymphatic-nervous temperament.

The moral condition of lunatics.—Most of the premonitory symptoms of insanity are evidentiary of a change in the moral constitution of the individual. The best warning is given by a metamorphosis of the natural character, of a permanent and remarkable description. The subject of this alteration has, as it were, turned his back upon himself, and becomes the opposite of what he formerly was. A diffident and retiring man will be found making some extraordinary exhibition of himself at a public meeting, to the amazement of all his acquaintances; or, perchance, he takes to writing and publishing productions in which he makes manifest to the whole world the symptoms of approaching disorder. I have known the *cacothetes scribendi* to be a premonitory symptom of madness in many instances; private matters and domestic occurrences being laid before the public in newspaper advertisements, placards, and hand-bills; nor is it an unusual discovery to find an insanely-poetical manuscript in the repositories of one who has just become lunatic. A man whose natural disposition it was to be very timid and cautious in the prosecution of his business affairs, will, in the moral disorder, which gives the first warning of diseased understanding, be found plunging into all manner of rash speculations and hazardous stocks, or even turning projector of the most bold and startling schemes. Changes of profession, pursuits, and religious persuasion, are other modes in which the alteration of disposition and temper manifests itself. A sudden passion

* In upwards of 1000 cases of insanity occurring in this quarter of the country,

{ 48 per cent were males.			
{ 53	"	"	females.
{ 75	"	"	between 20 and 50 years of age.
{ 51	"	"	had the nervous temperament dominant.

{ 5	"	"	sanguine " "
{ 17	"	"	temerarious " "
{ 29	"	"	—

for intoxicating liquors, contrary to all former habit, is also not unfrequent evidence of threatening insanity. In short, the sober man often becomes intemperate; the prudent, rash and extravagant; and the sedate and reserved, noisy and wild,—dispositions being acquired which seem opposed to the natural character. Changes, even in a desirable direction, if sudden, unaccountable, and extreme, are equally suspicious. I have known in such circumstances the intemperate to become, not merely temperate, but abstinent; the dull and heavy to seem active and intelligent; the careless, pious; and the timid, courageous; each of these spurious amendments foreshadowing the mental eclipse. Such reversals as described, occurring in those hereditarily predisposed, you may consider as indicative of explosion; and if you act opportunely as a physician, you will lessen the probability of your being required as a medical jurist.

Though a change of this description is the usual precedent of the intellectual disorder, still the moral aspect of the unsound mind is not always of the antipodean character. When insanity does occur without this sort of forewarning, the emotional features of the disease are then as likely to be a caricature of the natural outline of the patient's disposition. Passions which had stamped the mind in the state of health become dominant in a state of disease in which the voluntary power over their exhibition is impaired or suspended,—constantly diminished. The naturally ambitious man, who in his heart worshipped wealth and station, stands forth confessed and bare; he becomes a king, or at least the possessor of enormous wealth. The vain female, whose chief objects in life were dress and adulation, becomes a queen, and is alchemist enough to convert any paltry convocation of rags and straw into a crown. When insanity is marked by the predominance of some one passion, it is more broadly displayed than it ever is in a sane being; and the natural language of the emotion is such as no caricaturist could exaggerate. Such moods are, however, not generic, but special phenomena, and are seen in certain varieties of monomania. Our business at present is rather with those feelings which affect the moral portrait of every lunatic, and of these one of the best marked is selfishness.

Selfishness is one of the most prominent features of the unsound mind. A great many moral defects are comprehended in this term. It implies the decline or destruction of the best part of our social nature, the loss of the sympathetic and benevolent emotions, and, in consequence, a less control over much that is ugly and hateful in humanity. Such feelings seem

to be a finer part of the moral constitution, for they are ordinarily the first to suffer from the approaching malady, and the last to be perfectly re-established. "In many persons thus situated," says Dr. Thomas Mayo, "in whom, at the time at which the inquiry is made, the reasoning powers are in a clear and sound state, and whose emotions are flowing easily and quietly, we are enabled to detect disease by observing that the patient is not going along or sympathizing with us, or, indeed, with any one extrinsic to himself. Perhaps his conversation can only be characterized as morbid by its remarkable want of relation to all that is passing in the minds of bystanders. In this point the insane are remarkably contrasted with the inebriated, whom in many points they greatly resemble. Persons in the latter state overflow with sympathy, and carry it to a ridiculous extent."

We usually find that alteration or disappearance of the natural affections has been one of the earliest symptoms that attracted attention. In a lunatic you will generally observe that the ties of consanguinity are snapped, and that no interest is manifested in the welfare of friends; the mother may have forgotten her child, and the wife her husband. It is well if the loss of affection have assumed no other than a passive character, for it very frequently happens that they to whom they most owe affection are those whom the insane visit with their hatred and their violence. To them their fancied ills are attributed; but even when their relatives are not mixed up with their delusions, they are usually treated with aversion or with apathy. Not only are the natural affections lost in the overwhelming tyranny of selfishness in the insane mind, but so also are those social feelings which unite men to each other. Kindness, compassion, friendship, and sympathy, are not amongst the virtues of the insane. In an asylum you will not find much association among the inmates. It is no uncommon thing to see in a confined airing-yard twenty or thirty people walking about, and no two keeping company together; and in a day-room of lunatics there is very little conversation. Each one is willing enough to speak of his own delusion, or to discuss the particular injustice of his own imprisonment, but he has neither ear nor heart for the complaints of his fellows. They are under circumstances which might be expected to bind men strongly to each other, but they are not so bound. They are under circumstances which the multitude of them deem to be the consequences of unheard-of injustice and oppression; and with this powerful incentive to social action they are directed, controlled, and superintended by a very few, without ever attempting to re-

gain the freedom which they all desire so much by any effort of co-operation. They do not combine or conspire together, not from want of intellect, but from the decay of all social and sympathetic feelings. In many hospitals the walls are so low that, though they prevent an unaided person from escaping, they are quite capable of being scaled, if the person making the attempt had only the aid of one sympathizing individual; yet the insane never make their escape in this manner. The lack of the benevolent affections miserably curtails the happiness of life; and since so many of the insane have, from this moral deficiency, no active sensation of happiness, we cannot wonder that a propensity to self-destruction is so common amongst them.

CONCLUSIONS RESPECTING THE SEAT AND NATURE OF ANGINA PECTORIS. BY DR. KNEELAND, U.S.

DR. KNEELAND draws the following conclusions from his researches into the nature and causes of angina pectoris:—

1. From the symptoms and morbid appearances, angina pectoris is not a disease of the lungs, heart and its vessels, or stomach, but an affection of the nerves supplying these organs.
2. Anatomy, physiology, and pathology would lead us to place the seat of angina pectoris in the par vagum, and not in the sympathetic system of nerves.
3. Like other nerves, the par vagum may be affected with neuralgia and rheumatism, with inflammation; it may be compressed by morbid growths; its spinal origin may be compromised by hemorrhage, accidental wounds, and various irritations—all of which may cause the symptoms of angina pectoris.
4. Angina pectoris and asthma are intimately related: the former being an affection more especially of the sensitive filaments of the par vagum; and the latter an affection of its motor filaments. Both are generally more or less combined in the same case.
5. Angina pectoris is a disease not necessarily fatal, especially in young persons, if accurately diagnosed, and properly treated.
6. In addition to the remedies of the books, special attention should be given to the inhalation of oxygen, and to the use of electricity.
7. In cases of angina pectoris, attention should be directed to the examination of the par vagum, from its origin to its terminations, which, doubtless, on careful examination, will exhibit lesions sufficient to account for a fatal result.—*American Journal of Medical Sciences*, Jan. 1850.

Original Communications.

ON INFLAMMATION AND ABSCESS OF THE UTERINE APPENDAGES.

BY MATTHEW JENNETTE, M.R.C.S.

Surgeon to Birkenhead Hospital.

HAVING met with, in the course of my practice, several cases of pelvic abscess in the female, more particularly after parturition, it may not be useless to direct the attention of the profession to the subject. I am the more induced so to do, as I find that in our British works on midwifery and post-partum diseases it is generally lost sight of, or else very slightly alluded to. It is one, however, of great importance, calculated to give the practitioner much chagrin and uneasiness, requiring nice tact in the diagnosis, and great attention as regards its treatment. Although our systematic writers have been comparatively silent on the subject, several very valuable papers have of late years been published upon it in the medical journals; as, for instance, by Dr. Doherty in the 22nd vol. of the "Dublin Journal;" Dr. Churchill in the 24th vol. of the same Journal; Dr. Lever in "Guy's Hospital Reports" for 1844; Bell, "MEDICAL GAZETTE," 1846; Battersby in the "Dublin Quarterly," 1847; and Dr. H. Bennet in the "Lancet," 1848; besides several cases scattered through the medical literature of the day: nevertheless, it is a subject which I fear is still very much overlooked, and one that is not as generally known in this country as its importance deserves.

While the disease in question has been comparatively so neglected or unknown to us, it is evident from the writings of Paulus Ægineta and others that pelvic inflammation and abscess in the female, its symptoms and sequelæ, as well as its treatment, were known to the ancients. French pathologists in the 17th and 18th centuries also directed their attention very much to the subject; the earlier writers among them, however, considering the purulent abscesses as of the womb, and more recently, from Puzos to Petit, adopting the fanciful theory of metastatic depôts of milk to account for their existence: within the last 30 years, however, more correct

views have been adopted by our Gallic neighbours, and much and valuable have been the amount of their writings and research on the subject,—among others by Dupuytren, Velpeau, Grisolle, and Marchal de Calvi. For more particulars as regards the historical development of our knowledge on the subject, by the French, I refer to the valuable papers of Drs. Battersby and Bennet, referred to above.

Notwithstanding all that has been done to elucidate the subject even by the French, there is still much field for investigation, which Dr. Bennet attributes with much truth to the fact of its being almost altogether studied with reference to the puerperal state, although pelvic phlegmonous inflammation is far from being uncommon apart from that condition; yet as it is generally the case that in the former it appears in its severer form, the milder type of the latter state is overlooked. We know, for example, that puerperal metritis is of a type much more intense than inflammation of the womb unconnected with pregnancy—a fact explained by Marchal thus. The process of pregnancy induces (so to speak) a fibrinous diathesis, the fœtus requires a constant supply of fibrine; and the female system in consequence of this demand acquires a singular tendency to the secretion of this formative element; but it is unfortunately at the same time the essential material of inflammatory action, and thus it is, that the very condition that gives the maternal system the power of supporting the life of the young being, is the prolific source of many ills and sufferings; thus, although the *pus en nature* is never existent in the blood, and therefore can never be transported by metastasis to any local seat of inflammatory action, the elements of the fœtus are present in it during the progress of foetal development. Keeping this idea in view, we may be inclined to regard with more favour than is fashionable now-a-days, the old theories about “milky deposits,” “metastatic collections,” &c. Another evil consequence has resulted from the overlooking the non-puerperal form of the disease; extreme cases only being in general recorded, which has among others misled the otherwise accurate Marchal de Calvi, in giving it as his conviction that the non-puerperal abscess is generally fatal, and that it as often points by the abdominal walls as by the bowel

or vagina, which is decidedly erroneous.

To understand the seat of the disease properly, it is necessary to recollect how the peritoneum, in passing from the posterior wall of the bladder on to the uterus, and thence to the rectum, forms two large folds (the lateral ligaments) containing within them the Fallopian tubes, ovaries, and round ligaments, as well as a large quantity of areolar tissue connected, although in a great measure distinct from the extra-peritoneal cellular tissue of the pelvis. Thus in the cavity of the pelvis immediately in contact with the uterus, between the peritoneal folds, but external to them, and connected with the bladder and rectum, we have an abundant supply of that tissue which of all others is most prone to inflammation; together with other important organs, more or less disposed thereto. Hence the pathological understanding of pelvic inflammation of this part is so easily acquired: it is strange the subject was not long since fully developed by our systematic writers, particularly of the midwifery class. The inflammation may of course attack any one of the uterine appendages in the first instance, but generally in all probability the loose cellular tissue in which they are lodged; it then may extend to the others in succession; the peritoneum, however, in non-puerperal inflammation, seldom is affected, whilst in the post-partum variety that membrane is particularly liable to inflammation.

Causes.—In the non-puerperal state the disease may be produced by anything calculated to increase the vascularity of the part, or arrest the functions of the uterine system; chronic inflammation of the uterus, or direct injuries (well illustrated by a case of Dr. Bennet in the “Lancet” for 1848) but more especially by the arrest of menstruation—a good example of which is a case by Mr. Bell, in Vol. II of the “Medical Gazette,” New Series. The menses being arrested by exposure to cold, an abscess was formed, which ultimately discharged through the vagina. The case was, previously to Mr. Bell seeing it, attended by three medical men, who successively treated it for strangulated hernia, continued fever, and inflammation of the bowels. These mistakes, I suspect, are far from being uncommon, and hence many cases of non-puerperal phlegmon of the uterine appendages are treated for,

or considered to be something else,—as neuralgia, hysteria, uterine irritation, or rheumatism, and many examples from respectable sources confirmatory of this suspicion could be deduced; as a case from Mr. Taylor, on rheumatism of the uterus, which I abridge. Mrs. H.—aged 24, had a miscarriage during her second month: eight days after she exposed herself to a privy: next day she had great bearing-down pains, frequent desire to pass water, which she did with excessive pain, and very little at a time; great pain above the symphysis pubis, the pressure of the hand insupportable, fever, no discharge from vagina, uterus hot and tender, could not lie but on the back, &c. The treatment was antiphlogistic, and she gradually recovered; a profuse *fluor albus* appearing at the same time. Two of the cases recorded by Churchill are non-puerperal, as well as one of the eight narrated by Mr. Bell; in the sequel I will give examples of the same variety. Various circumstances connected with parturition may predispose the parts concerned to become affected by this disease; as impatient interference, resulting perhaps from want of sufficient confidence in the efforts of nature, premature or too long delayed mechanical aid, turning, removing with the hand in the uterus the placenta, exposure to cold, falls, blows, &c.: it may follow an attack of acute inflammation, or be a sequent of puerperal fever, as is illustrated by one of Lever's cases. Dr. Copland, in his admirable article on puerperal diseases, in his Dictionary (in which, by the way, the disease I am treating of is all but unnoticed) introduces some remarks relative to the modern use of anæsthetic agents in midwifery, which I think is equally applicable here; he considers their use as not altogether innocent; immediate fatal results may be prevented, but can we so prevent other consequences? Anæsthetic agents have been demonstratively shown not only to produce insensibility, but also congestion of the lungs, and subsequent death in a short period; witness the case of the late Dr. Anderson of this town (vide "Lancet," Vol. ii. p. 99, 1848). In nine out of ten, or nineteen out of twenty cases, no unpleasant result may take place, but the tenth or twentieth may be a serious puerperal disease; it may be the one we are writing about.

Symptoms.—I will describe those of the puerperal variety, the non-puerperal

being (child-bed apart) of the same nature, but generally milder in intensity, more chronic in character, and the abscess seldom opening through the abdominal parietes, but generally through the vagina or rectum; hence it is so often overlooked, the discharge through the vagina being looked upon as a copious discharge of whites, and that with the fæces being still less liable to be observed. The symptoms may commence two or three days after delivery, or not for several weeks, generally with a rigor, or a succession of shiverings; there is more or less fever, occasionally remitting; pulse varying from 90 to 110; pain in the abdomen; the patient generally feels better in the morning, with increase of fever in the evening; the uneasiness and pain increase as the disease advances; sometimes there are pains resembling sciatica in one or both legs; painful micturition, and tenesmus occasionally of a most distressing character; the secretion of milk generally is suppressed, the lochia sometimes; tongue is coated; the patient becomes emaciated, is subject to hysterical paroxysms, frequently vomits, and sweats profusely on falling to sleep. These symptoms, inasmuch as the formation of pus in phlegmon of the iliac fossa is remarkably slow, may continue for a considerable time if overlooked, or not relieved, until the matter is evacuated either by a natural or artificial opening. On examining the abdomen, it will be found, that although the patient complains of pain all over it, pressure over the pelvic portion aggravates it, while elsewhere it relieves it; showing that the general pain is neuralgic, whilst the local proceeds from inflammation. In one or other iliac fossa will generally be detected by the touch a tumor with a brawny hardness, but not always, as in one of my cases which is hereinafter described: but in every case it may be detected, and the true nature of the disease known, by *vaginal* or *rectal* digital examination. To examine by the former outlet, it is advisable that the patient lie on her back, with her legs drawn up, when, on carefully introducing the forefinger of the right hand, while with the left hand you press over the iliac fossæ, you can easily detect the tumor, and even, if supuration has not yet taken place, the roof of the vagina will be found, as Dr. Doherty so well expresses it, "as firm and inelastic as a deal board"—a very

important evidence, as, when we know the true nature of the case, we may hope by appropriate remedies to cause resolution, which several recorded cases show to be quite possible; as, for instance, the case recorded by Doherty himself, and others in Dr. Churchill's paper. If further evidence is required, examination by the rectum in a similar way, the patient however being placed on her side, will afford it. It has been stated by some writers, Lever for example, that the disease is more frequent on the left side than on the right; but, as far as I can find by reference to published cases, I think it is equally liable to attack either: thus, out of forty-one cases, nineteen were on the right, nineteen on the left, and three on both sides.

The terminations of the disease may be, 1st, resolution, which is of course the most favourable, and one which we may reasonably expect to induce, provided we ascertain the nature of the disease before it becomes too far advanced: hence, examination with the finger in the vagina or rectum is so important, and also the great error of attributing too hastily and without careful examination, painful affections of the iliac fossa or abdomen after parturition, to neuralgia, irritable uterus, &c. Puzos, Marchal, Churchill, and others, relate several cases where this happy result took place. 2dly, suppuration. When either through neglect or the inefficiency of the remedies employed, resolution does not occur, an abscess is formed, the purulent matter of which is said sometimes to be absorbed, but more generally it finds its way either externally through the abdominal walls covering the tumor, into the peritoneum, after giving rise to fatal peritonitis, into the vagina, bladder, rectum, or uterus, and sometimes through the femoral ring or thyroid foramen. Among 37 cases in which the matter escaped, I find 11 opened through the vagina, 9 by the abdominal walls, 5 by the bladder, 3 by the inguinal ring, 3 by the rectum, 3 into the peritoneum, 1 through both vagina and rectum, 1 into the uterus, and 1 through the thyroid foramen. These proportions cannot be considered conclusive, inasmuch as the number of cases are too few to decide. 3rdly, the intensity of the disease, or the secondary affections induced by it, may prove fatal after an indefinite time.

Diagnosis.—The vaginal examination is in itself sufficient to distinguish this affection from any other: however, inasmuch as this will not always be permitted, and the disease has been from time to time mistaken for others, it is right to study its peculiarities; particularly as, when it occurs independently of child-birth, or a considerable time after, it may not be so reasonably expected. Abscess of the abdominal parietes may be distinguished from it, by causing the patient to lean on her knees and elbows, when the tumor will be found to move with the parietes, while in iliac abscess you can move them over it. The pressure of the tumor on the nerves may cause pains resembling sciatica, but a careful examination, together with the history of the case, ought to be sufficient to show the nature of it. In like manner may be distinguished lumbar abscess, pregnancy, &c. From peritonitis it is easily distinguished by the neuralgic pain and several of the symptoms of peritonitis being absent: however, peritonitis may occur as a consequence of the disease in its advanced stage; either on account of the abscess bursting into the peritoneal cavity, or in consequence of the extension of the inflammation from the uterine peritoneum. But this only occurs when the disease has existed for some time, and is easily known by the aggravation of the pains and fever. I have known it to be mistaken for hernia, and considerable pressure used for the reduction of the supposed rupture with apparent effect, owing perhaps to the mobility of the parts within the abdomen: but it is easy to imagine how such a proceeding might cause rupture of the abscess, and extravasation of its contents into the peritoneum. I will give in the sequel a case of M. Dupuytren, where it possibly might be mistaken for aneurism.

Prognosis should be guarded, inasmuch as peritonitis sometimes occurs from the matter finding its way into the abdominal cavity: besides, when it discharges through the vagina or elsewhere, fistulous openings may remain, and the flow last for a time long enough to cause the patient to sink; and it also sometimes happens that the disease returns when the uterine functions are again called into play. Mr. Bell found, in 93 recorded cases, as

many as 22 deaths, which I think is more than the average mortality.

As to the sequelæ, I think it not improbable that future miscarriages may be induced, but in one of my cases the individual has had several children since, all at their full time, and has had no return of the disease; of the other consequences mentioned by writers I cannot speak.

Treatment.—The indications are two fold. To produce resolution, if possible; if not, suppuration and evacuation of the matter as soon as possible. Several published cases prove that resolution will often occur under proper treatment; we must remember at the same time that patients with this disease will seldom bear heroic remedies, as general bleeding, &c.: a dozen leeches, applied two or three times if necessary to the seat of pain, or a smaller number to the vagina, by means of the speculum, poultices, fomentations, injections of warm water into the vagina and rectum, and mercury so as slightly to touch the gums, may succeed in arresting the progress of the inflammation: the secretions must at the same time be attended to, not inducing, however, much purging, which gives pain: light bland food is to be given, opium may be necessary sometimes to soothe the pain, and in the form of enema or suppository is very useful for relieving the tenesmus, which is often very troublesome. If we do not succeed in arresting the inflammation, and that it is evident suppuration has taken place, we must endeavour to promote the formation of pus and its discharge. Poultices and fomentations are to be persevered in, and the abscess opened as soon as possible; this may be done either through the abdominal walls, through the vagina, by means of a speculum and guarded lancet, or through the rectum by means of a trocar and canula; and it will be right to select for operation that part to which, in the individual case, the matter is nearest, and the abscess most closely connected with: for instance, in the two cases in which I opened the abscess in the hypogastria, the matter was evidently pointing in that direction, but I think the vagina or rectum would be most eligible if the matter pointed in either of those directions. If there be no adhesion between the tumor and the abdominal parietes, I think the adop-

tion of Graves's plan, as recommended by Churchill, or that of M. Martin, to excite adhesive inflammation, objectionable, as, besides other reasons, such a proceeding would occasion delay, the matter possibly in the meantime finding its way into the peritoneal sac, and so inducing perhaps fatal inflammation. After the matter is discharged, of course the patient's strength must be kept up with generous food, wine, &c.; and, should any hardness remain, small doses of potass. hydriod. in decoct. sarsap. &c. should be administered.

CASE I.—Mrs. J —, aged 24 years, confined of her second child, 4th June, 1844: labour in every respect natural, and of short duration: after a few days she was able to resume her household duties, which she did without sufficient care. On 23rd, being warm from over-exertion, she exposed herself to a current of cold air; after which she had several attacks of shivering: the milk diminished in quantity, pain in the lower part of the abdomen, shooting down the left leg began to be felt; fever, with nightly exacerbations, set in. These symptoms were borne for some time, and I was not sent for until the pain assumed great intensity. I saw her July 1st, when she was suffering very much from pain in the left iliac fossa, with her legs drawn up: pulse about 110. I could detect no tumor in the iliac fossa then: indeed, she would not allow me to make sufficient pressure to ascertain the fact. I easily ascertained by vaginal examination the nature of the disease, and ordered a constant succession of poultices after leeching, aperients, and opiates to soothe the pain. The symptoms increased in intensity, when in a few days a brawny hardness was perceived in the iliac fossa. Poultices matured the abscess, which I opened through the abdominal walls on the 24th July; it freely discharged, and the opening healed in a few days: her recovery was slow but permanent: the child, however, had to be weaned, she never recovering her supply of milk. She has had three healthy children since, and no return of the disease.

CASE II.—Hannah Phillips, aged 36, admitted a patient of the Birkenhead Hospital and Dispensary, May 31, 1850. Says she was delivered of her sixth child five weeks before, by a midwife: that she had suffered very much at the time, particularly in her right flank, which

part gave her great pain for about five weeks previous to her confinement, which she attributed to over-straining herself: she states that the woman who attended her said that the after-birth "stuck fast," and that she did something, which gave her great pain, to remove it: believes she passed her hand into her; but her sufferings were so great, she is not sure of that. She now complains of great pain in the lower part of the belly, particularly on the right side; can only lie on her back, with her legs drawn up: she is worn and emaciated, with hardly any milk; has a constant desire to sit on the commode, with a feeling as if there is something to come away, although her bowels are frequently moved, but with great pain. When she falls asleep, she is bathed in a profuse perspiration; pulse about 100, soft and small. On examination externally, there was not, as in the last case, any hardness to be felt, but only an indistinct evidence of a deep-seated fulness, but not sufficient *per se* to indicate an abscess, which, however, was fully recognised by examination by the rectum, where the cause of the tenesmus was found to be a fluctuating phlegmon. Fomentations and poultices were applied; mild restoratives and opiates ordered: and on the 8th of June, while sitting in the night-chair, a large quantity of pus came away through the rectum; after which she experienced great relief. Light nourishing food and tonic medicines were prescribed; under which treatment she continues to improve in health and strength, being, however, unable to afford her child its natural nourishment.

CASE III.—March 27th, 1850. Attended Mrs. M—, a stout, strong woman, about 33 years, living some distance from here, in labour of her fifth child, which was, in every respect, natural and quick, requiring no interference on the part of the accoucheur. She was subsequently attended by a medical gentleman of her neighbourhood. I was sent for to see her on the 7th of June, when I found her much altered in appearance, thinner, complaining greatly of a severely painful lump in the right iliac region, which, at the commencement of uneasiness there, which was about a fortnight after her confinement, was treated by leeches, for inflammation of the iliac veins, and which latterly had been supposed to be

hernia; she being directed to procure a truss. The constitutional symptoms, though of a much milder form, were the same as in the last case: neither was there the same amount of tenesmus or difficulty of making water. I found the same brawny hardness as in the first case, and ordered her effervescing saline draughts, and repeated hot poultices of linseed meal, which, in a few days, forwarded the abscess so as to enable me to open it, which I did, giving exit to several ounces of healthy pus, which gave great ease; after which, with proper nourishment, she quickly convalesced.

(The two following cases of Professor Dupuytren are abridged from the *Journal Hebdomadaire de Médecine*, Tome 6.)

CASE IV.—(Non-puerperal). A young, well-formed woman was affected for some time with a malady having its seat in the pelvis, for which she could assign no cause: she had severe pains in the neighbourhood of the bladder and rectum, and in the groins. A physician she consulted considered her suffering from diseased uterus; but on admission into the *Hôtel Dieu*, in January 1829, and examining with the finger in the vagina and rectum as high as possible, and strongly pressing down with the other hand on the epigastrium, a painful tumor was perceived. She was submitted to antiphlogistic treatment, hot baths, cataplasms, &c.: after a few days the pain suddenly disappeared, without at first being able to account for this quick cessation: however, it was soon apparent that the urine contained a large quantity of pus, the emission of which was without pain or inconvenience. The discharge had not quite ceased when she left the Hospital. Dupuytren introduces this case with some interesting remarks on the manner in which abscesses open into hollow organs, which he shows to be valvular, as that of the ureter into the bladder, not allowing of the passage of the contents of the organ into the abscess, but permitting of the latter closing on being emptied of its contents.

CASE V.—A woman, two months confined, aged 36, was admitted into the *Hôtel Dieu*, November 2, 1829. She complained of pain in the right iliac fossa, where was a considerable swelling: no fluctuation could be detected: she could not extend the limb without great pain. Antiphlogistic treatment was di-

ected. After fifteen days, Dupuytren perceived deep-seated fluctuation. Mons. Capuron and others could not do so, which caused Mons. Dupuytren to delay the opening which he intended to make. Some days passed, during which a phenomenon supervened which tended to weaken the diagnosis of Dupuytren; the tumor became less painful and voluminous, at the same time, no discharge of pus taking place, either by stool, vagina, or bladder: however, soon the tumor resumed its former volume, and fluctuation became evident: it was now resolved to operate. M. Dupuytren made a small incision with a straight bistoury, below the crural arch, outside the femoral artery; a small quantity of pus escaped by the edges of the instrument, on withdrawing which, and introducing a female catheter into the abscess, an enormous quantity of matter was discharged, with great comfort to the patient. The matter continued to be discharged, the catheter requiring to be once more introduced, when some obstacle opposed its free exit: by degrees the discharge lessened, and she was discharged, cured, about the end of December, 1829.

CASE VI.—(Abridged from *Journal Hebdomadaire de Médecine*, Tome 3). A young woman, confined a month, was admitted into the *Hôtel Dieu*, April 7, 1829. She was seized, a few days after her delivery, with severe pains in the right iliac fossa, extending down the thigh, and rendering her unable to walk. A tumor afterwards showed itself in the fossa, extending into the groin through the femoral ring. On examining the tumor, which indicated fluctuation, M. Dupuytren perceived it to be the seat of strong pulsations, corresponding with the pulse, which extended from its inferior part to Poupart's ligament: these pulsations were remarkable along the anterior and middle part of the tumor, and also transversely along the superior and right portion of it. M. Dupuytren attributed these symptoms on the middle of the tumor to the presence of the superior portion of the crural artery; and the transverse beats to that of the circumflex artery, the pus the abscess contained having passed behind the vessels, by means of the lax cellular tissue so abundant in that situation. The next day the pulsations had disappeared; which he attributed to altered position of the arteries, in consequence

of the numerous examinations made by the pupils: however, he plunged a bistoury into the tumor outside and in the angle formed by the union of the crural and circumflex arteries. Some ounces of healthy pus escaped; but, owing to the sinking of the crural arch, which had been raised by the pus, the discharge became arrested. He then introduced a female catheter, by which he emptied the abscess: a mesh was then introduced, and the case progressed, in every way satisfactorily, to a complete cure.

CASE VII.—(*Désormeaux*, *Journal Hebdomadaire de Médecine*, Tome 7). D.—, 24 years, healthy during pregnancy, was delivered, January 13, 1830, after a painful labour of thirty-six hours, of a dead child; the second succeeding day slight pains were experienced in the abdomen, which, by appropriate remedies, were relieved, leaving, however, an uneasiness and feeling of weight about the rectum.

Feb. 1st.—Diarrhoea came on, the defecation being accompanied with much pain: by examination with the finger in the rectum a tumor was discovered to the left side of the gut; examination by the vagina also showed the existence of a tumor: leeches, &c. were prescribed; but the tumor increased more and more. M. Désormeaux was about opening the abscess, when it discharged itself, by the vagina, of a quantity of foetid pus, with great relief; when suddenly, on the 9th of February, very acute peritonitis set in, which soon ended in death.

At the post-mortem, the peritoneal cavity was found to contain a considerable quantity of phlegmonous pus, the stomach and intestines being healthy. The vagina being opened on its left side, was discovered an ulcerated opening, which led into a purulent cavity at the side of the vagina and rectum, the cellular tissue in the neighbourhood being extensively destroyed.

In the *Provincial Journal* for 1844, are several cases recorded by Mr. Edrington, of Birmingham,—one in particular, where abscess of the right iliac fossa recurred after different pregnancies, each time discharging by the bladder, the poor woman having also had very numerous miscarriages. In her case there was pain in the right iliac fossa before marriage: so that it may be considered as one of non-puerperal disease, aggravated by uterine excitement.

Birkenhead, July 2nd, 1830.

AN INQUIRY INTO THE
VIEWS OF CERTAIN MODERN
PHYSIOLOGISTS RELATIVE TO
THE LAWS AND ACTION OF
THE NERVOUS SYSTEM—
CEREBRAL, SPINAL,
AND GANGLIONIC;

AND HOW FAR SUCH VIEWS ARE SUB-
STANTIATED BY THE PHENOMENA
PRESENTED TO OUR OBSER-
VATION IN HEALTH AND
DISEASE.

BY WILLIAM SMITH,

Member of the Association of Medical Officers of
Hospitals for the Insane; formerly Resident
Surgeon in the Lincoln Lunatic Asylum, and
subsequently in the General Hospital at Lin-
coln.

DURING the last five months, whilst preparing the materials for the papers lately published in the *MEDICAL GAZETTE*,—"On the present state of lunacy and lunatic asylums, and on the nature and treatment of mental derangement," my attention has been almost exclusively directed to the physiology and pathology of the nervous system: many interesting phenomena, scarcely, if at all thought of, prior to that investigation, have forcibly and irresistibly rivetted my attention. The members of the Medico-Chirurgical Society of Nottingham, in addition to their urbanity and kindness in allowing me, an utter stranger, and unconnected with their efficient society, to take up their invaluable time, have unwittingly rendered me a service of still greater magnitude: by opposing very strongly the doctrines then propounded by me, they have set me upon a course of deep reflection. Believing most conscientiously that those views were strictly in accordance with the truth, and having had most ample opportunities (in the Lincoln Asylum and elsewhere) of seeing insanity, (and what are usually termed) nervous disorders, upon a large scale, in several different counties of England, I sat myself down to a careful and deliberate investigation of some of our most celebrated authors, in order to collect together into a narrow focus such views as appeared corroborative of, or not greatly dissimilar to my own. Although I had previously, on several occasions, read with much interest the

excellent volumes of Mr Travers, on "Constitutional Irritation," their perusal latterly has interested me more than ever. To the young surgeon just entering upon the gulfs and whirlpools, the *Scylla* and *Charybdis* of surgical practice, they are invaluable. Although no longer to be ranked among the juniors (seeing that my hair is now assuming a silvery tint), I have within the last two months strengthened my arguments most materially by facts and deductions contained in those carefully digested volumes. It would appear that Dr. Calvert Holland, in his *Philosophy of Animated Nature* (a not very favourable and, as I think, rather harsh review of which appeared in the *MEDICAL GAZETTE* not long ago), has merely enlarged upon and carried out in extenso many of the doctrines therein communicated. Mesmerism, however, is evidently a new birth; whether a legitimate offspring or of a surreptitious and spurious race, I leave to the worthy and learned doctor and his readers to decide. The philosophy has taken me a long time to study and digest, &c. There is an abundance of really valuable matter, and numerous experiments by various physiologists, most accurately given, with valuable deductions therefrom. Many of his views, or something vastly like them, are to be found in Dr. Henry Holland's *Medical Notes and Reflections*. Dr. Calvert Holland however, is more ultra in his opinions than either of the authors just named.

During my late investigations into the laws and actions of the nervous system, one thing has particularly struck me, viz. that modern physiologists, in their eager desire to enter minutely into a description of every portion of the nervous system, have carried their love of specializing too far, and thus made the separate parts of one system or unity to have an action altogether independent of, and beyond the cognizance of, the rest. This I believe to be the grand error—the besetting sin, of the present scientific age.

That sagacious and most experienced physician, Dr. Latham, in the preface to his excellent "*Clinical Lectures on Diseases of the Heart*," has observed:—"The study of our times has been to specialize and to localize disease, and it has had very useful results. But it

has had a tendency to narrow our views and to cripple our practice, by setting up as many several pathologies within the body as there are several organs. Yet no sooner do the diseases of different parts come to be treated, than they begin to claim their place in a common pathology. We cannot reach them and apply our remedies directly to them, in the isolated spots wherein we find them; but if they are to be reached, and treated at all, it must be through the vascular system, or through the nervous system, or through the digestive and assimilative system. For these are the common agents of life and increase, both healthy and unhealthy, and the common channels both of food and of medicine."

Now according to my ideas of the present state of knowledge relative to the physiology of the nervous system, the remarks of this accomplished physician may be brought to bear, with equal force, upon the present artificial and (as I think) most unnatural distinctions attempted to be made in the physiology of the nervous system. If we are to resign ourselves blindfold, and with implicit faith and confidence, into the hands of these imaginative gentlemen, who assert that the brain is the special and exclusive domain of the psychical principle; that the spinal cord has its *vis nervosa*, and is the *arbiter elegantiarum*—the high and mighty potentate, whom spasms, convulsions, and other lady-like diseases obey; that the sympathetic or ganglionic system is merely the larder or store-room from whence the various organs, tissues, &c., receive their nourishment, supplies, &c.; that the heart is not dependent in any way upon the nervous influence; that the muscular fibre contracts or displays irritability, not in virtue of any energy or principle derived from the nervous system, but simply from some *vis insita* or property inherent in itself;—if, I say, we are to adopt these views, we shall inevitably require a special pathology for each of these various organs and tissues: and this brings me to the exact argument advanced by Dr. Latham. It may perhaps appear the height of presumption in a medical practitioner (a sort of amphibious animal, like Falstaff's hostess neither fish nor flesh) like myself venturing to oppose the doctrines of learned physiologists; but, as far as my observation goes, these pro-

fessed authors, as a general principle, do not make good practitioners, and, *vice versa*, sound practitioners are seldom guilty of knowing much of the hidden mysteries of physiology. Had all the views of eminent physiologists been founded on facts, and deductions carefully and deliberately drawn therefrom, we should have had fewer discoveries in this department of science, and less theoretical knowledge to unlearn. A learned writer has well remarked, "How wild soever the wanderings, or great the departure from a strict logical procedure, the dreamy conjectures to which they give rise find naturally a home in the bosom of physiology."

Dr. Calvert Holland, in a recent work, "Practical Views of Nervous Diseases," has justly remarked:—"With the prevailing limited knowledge of the nervous system, how could the practitioner see the shortest road to the seat of the evil, even if familiar, which is not the general rule, with the doctrines of the physiologist?" By one school he is told that voluntary and involuntary motions are independent of any power derived directly from the nerves; that in fact they are the result of a *vis insita* in the muscular fibre: by another, he is taught that all these motions probably depend upon a *vis nervosa*, whilst the brain and its wonderful faculties have not the slightest connection with it, or with any nervous influence; the cerebrum being the exclusive domain of the physical principle. This immense organ, with which all parts of the nervous system are associated, from which it receives impressions, and to which it distributes the motive power, is, according to such reasoning, pervaded by no agent which is common to the whole. He is further informed that the functions of the nerves consist in conveying a series of vibratory movements, and that all vital phenomena are explicable on this view; or that the nerves do really transmit a something, but agreeably to what laws is not stated. He is, however, more frequently amused with the ingenuity and eloquence which demonstrate the perfect fallacy of all such opinions. The idea that the nervous system is animated by any power is ridiculed with pointed facetiousness:

"Is it possible, amidst this chaos of physiological doctrines,—this clash-

ing of conclusions on the nature of vital action, for the mind, how anxious soever it may be, to discover the direct road to the seat of disease? Which is the path, according to the received notions? One, groping in the search, acts energetically on the bowels, or thoroughly relieves the stomach of its contents; another detects the evil in the blood, and emits a copious stream; a third, ascertaining the dry state of the skin, determines the fluids in that direction. In none of these modes of treatment, or in others which it is unnecessary to notice, is there a clear and comprehensive view of the powers of life, or indeed a knowledge of the laws according to which they operate. This would point out the degree of efficiency which is exercised by each in the production of the morbid results, on an accurate conception of which all medical treatment must be founded. It would indicate to the practitioner the shortest course to the desired object."

I leave it to any person of reflective mind, conversant with the present state of medical science, and possessed of sufficient candour to speak the whole truth, to decide whether this be not a true and faithful picture of passing events and opinions. But if practitioners themselves are perplexed by such an *embarras de richesses*, as Mr. Travers not inaptly styles it, what is the state of the unfortunate medical student? How shall he escape the "*infames scopulos Acrocerania*," the "*mare turgidum*" of physiology? Verily, we may say with the elegant poet, "*Illi robur et es triplex circa pectus*" are needed for that man who dares to enter on the debateable land of modern physiology.

But let me illustrate my views by a quotation from one of the most eminent authorities of the present day. Dr. Carpenter, in his excellent Manual of Physiology, page 486, remarks:—"We have now considered the entire series of those operations which make up the vegetative or organic life of the animal; including the functions by which the germ is prepared, by which it is nourished until it can be left to its own powers, by which its continued development is effected until the fabric characteristic of the adult has been built up, and by which the normal constitution is maintained through a lengthened period,

so long as the necessary materials are supplied, and no check or hindrance is interposed, by external influences, to that regular sequence of change on which the continuance of its powers depends. In this survey it will have been perceived that the essential parts of these operations are, in animals as in plants, completely independent of the influence of that which constitutes the peculiar endowments of animals; namely, the nervous system.

"a. The reduction of the food in the stomach, by the solvent power of the gastric fluid, is a purely chemical operation, with which the nervous system has nothing whatever to do, excepting that it perhaps accelerates the process, by stimulating the muscular coat of the stomach to that peculiar series of contractions which keeps the contents of the cavity in continual movement, and favours the action of the solvent upon it.

"b. With the process of absorption, by which the nutritive materials, with other substances, are introduced into the vessels, the nervous system has nothing to do; this being a purely vegetative operation, partly dependent upon the simple physical conditions which produce endosmosis, and partly on a process of cell-growth.

"c. The assimilation of the new material, effected, as we have seen reason to believe, by another set of independent cells, can receive but little influence from the nervous system, and is obviously capable of taking place without its aid.

"d. The circulation of the blood, again, though dependent in part upon the impulsive power of a muscular organ, the heart, is not on that account brought into closer dependence upon the nervous system; for we have seen that the contractions of the heart result from its own inherent powers, so as to continue after it has been completely detached from the body; and that the capillary power, which is the chief agent in the movement of the blood in the lower animals, and which exerts an important subsidiary action in the higher, is the result of the exercise of certain affinities between the blood and the surrounding tissues, in which the nervous system can have no immediate concern.

"e. The act of nutrition, in which every tissue draws from the circulating

blood the materials for its own continued growth and development, and by which it incorporates these with its own substance, is but a continuance of the same kind of operation as that which takes place in the early development of the embryo long anteriorly to the first appearance of the nervous system,—namely, a process of cell-development and metamorphosis, which must be, from its very nature, independent of nervous agency.

"f. The same may be said of the secreting operation in general; for this essentially consists of the separation of certain products from the blood by cells situated upon free surfaces; which thus remove those products from the interior of the fabric.

"g. And the interchange of oxygen and carbonic acid which takes place between the atmosphere and the venous blood when brought into mutual relation in the lungs, and which is the essential part of the function of respiration, is an operation of a merely physical character, with which the nervous system can have no direct concern.

"h. Finally, the development of the reproductive germs in the one sex, and of the ova within which these are to be evolved in the other, the subsequent fertilization of the latter by the former, and the changes consequent upon that act, together making up the function of reproduction, may be all regarded as modifications of the ordinary nutritive processes; and are effected, like these, by the inherent powers of the parts concerned in them, at the expense of the materials supplied by the blood, without any direct dependence upon the nervous system."

"841. Still, although the various processes which make up the essential part of the nutritive operations in animals, as in plants, are no more dependent on any peculiar influence derived from a nervous system in the former than they are in the latter, it must be evident, from the details already given, that there must be in animals various accessory changes, which are requisite for the continuance of the former, and which can be only effected by the peculiar powers with which animals are endowed. Thus, to commence with digestion: this preliminary process, which the nature of

the food of the plant renders unnecessary for its maintenance, can only be accomplished by the introduction of the food into a cavity or sac, in which it may be submitted to the action of the solvent fluid. The operation of grasping and swallowing the food, wherever it is performed, is accomplished through the agency of the nervous system; and if it be checked by the loss of nervous power, the digestive process must cease for want of material. So, again, although interchange of gaseous ingredients between the atmosphere and the circulating fluid may take place with sufficient energy in plants and the lower animals, through the mere exposure of the general surface to the atmosphere; yet we find that, in all the higher animals, certain movements are requisite for the continual renewal of the air or water which are in contact with one side of the respiratory surface, and of the blood which is in relation with the other: for the direction of which movements, a nervous system is requisite. In the excretory processes, moreover, the removal of the effete matters from the body can only be accomplished in the higher animals by certain combined movements, the object of which is to take up the products that are separated by the action of the proper secreting cells, and to carry them to the exterior of the body, there to be set free; and these combined movements can only be effected by the agency of the nervous system. Lastly, in the act of reproduction the arrangement of the sexual organs in animals requires that a certain set of movements should be adapted to set free the germ from the body of the male, and to convey it to the ovule of the female; and further, that the ovum should be expelled from the body of the latter in a state of more or less advanced development. For these movements a special arrangement is made in the construction of the nervous system, and in the application of its peculiar powers."

However strongly it may subject me to the charge of presumption in thus daring to advance my views in opposition to those of so eminent an authority as Dr. Carpenter, still I cannot allow such doctrines as those just quoted to pass current without entering my respectful but decided protest against them. Although I may not feel disposed

to adopt in their totality and entirety the novel views of Dr. Calvert Holland, as enunciated in his "Philosophy of Animated Nature," yet I cannot but coincide with him on many important points, and in none more cordially than those wherein he maintains that the blood and nervous energy are indispensable to every vital function or action throughout the human frame. If these views be correct—and numerous facts and striking analogies may be adduced in support of them—what are we to think of the doctrines of Dr. Carpenter, who clearly and distinctly asserts (in his 12th Chapter, pages 486-7, 8), that digestion, absorption, nutrition, the circulation of the blood, secretion, excretion, respiration, and the interesting and most important changes concerned in the process of reproduction, all take place without the nervous system having any immediate concern in the matter? For my own part, I cannot help viewing such doctrines as medical heresies of a grave and serious character, calculated to mislead junior practitioners and the rising generation of medical men, who may now be in *status pupillari*, and therefore very likely to adopt implicitly, and without investigation, any theory propounded by so eminent an authority. As far as my own humble opinion is concerned, all my observation and experience of the human body, both in health and disease, irresistibly lead me to the conclusion, that the nervous system is very materially and intimately concerned in all the functions or actions alluded to by Dr. Carpenter; and, moreover, if I do not greatly err, many experienced and sagacious practitioners might be found, who entertain opinions very similar to my own on this subject. What I would ask, are the uses of that complicated and universally pervading element, the nervous system, which extends its numerous gauze-like filaments, and impenetrable net-work processes, over every minute particle of the human frame, *a capite ad calcem*, if not requisite for the maintainance of every vital function or action necessary to the animal economy? why should the heart, the lungs, the stomach, the uterus, and every other important organ in the body, be plentifully supplied with blood-vessels, and, furthermore, be abundantly furnished with filaments from the three great nervous centres—brain, spinal cord, and sympathetic—if their very existence,

their function (whether special or otherwise), and action, did not depend upon, and derive their origin from, the reciprocal or galvanic action of blood and nerve. Great part of my life has been spent in the discharge of duties connected with large public institutions; for more than fourteen years I have had ample opportunities of observing disease upon a large scale, and during the last four years I have been a hard reader: with the writings of Latham, Watson, Billing, Brodie, Travers, Graves, Burrows, Pinel, Conolly, and most of our standard writers on mental disorders, I am pretty accurately acquainted: I trust, therefore (after these preparatory trainings, after the approved fashion of pugilism, &c.), that it may be permitted me to have some sort of an opinion on these matters. It seems to me that a man may in some cases so far give way to authority, and be led away by an adulation of celebrated names, as finally to have no opinion of his own. That excellent physician, Dr. Latham, in his sensible little volume on "Subjects connected with Clinical Medicine," published in 1836, has the following pertinent remarks: "Knowledge may be an incumbrance as well as a help. Many men know more than they are able to wield. There is a point (I believe) in the acquisition of knowledge (and this point varies infinitely in different individuals) beyond which, if more be required, the whole mass becomes useless to its possessor. I am acquainted with men who never have done, and who never can do anything, because they know too much; and I am acquainted with men possessing comparatively small knowledge, so dexterous in its use, that they have ridden over the heads of others far, very far, their superiors in acquirement. Nothing is more common than to hear it said of some eminent and distinguished person, 'eminent and distinguished as he is, what would he not have been had he possessed the learning of such an one?' Whereas, if he had possessed one particle more of learning than he has, he would have been nothing at all; it would have weighed him down, and he would never have been heard of.

"Fortunate, indeed, is the man who takes exactly the right measure of himself, and holds a just balance between what he can acquire and what he can use, be it great or be it small."

But to return to our more immediate

subject. The perusal of Dr. Carpenter's excellent Manual of Physiology, has afforded me much valuable information; the style (unlike many works in this department of science) is remarkably clear, and it contains many references to actual disease: this I conceive to be an immense acquisition in works of this kind. Why not combine physiology and practice of physic in the same book (of what use is either separate?), as Sir Astley Cooper taught anatomy and surgery, together, in his excellent lectures? Look at the illustrious Sydenham, who ridiculed the idea of anatomy *per se*, asserting that it was fit only for a painter: and yet show me a physician of the present day who can give a more graphic portrait of disease. I have in the course of my professional life, spent in several widely-separated counties of England, become personally acquainted with some minute anatomists and crack operators, men who could carve the human body to a nicety; and yet, in medical affairs requiring a little nice discrimination, or clear perception of matters going on below the surface, they were immediately beyond their depth. Such men should live in the butcher's shambles (or, Nero-like, transfix flies), for they literally revel in blood! "Tis their vocation, Hal!" The learned Schiller has remarked—"a physician whose horizon is bounded by an historical knowledge of the human machine, and who can only distinguish, terminologically, the coarser wheels of this piece of intellectual clock-work, may perhaps be idolised by the mob; but he will never raise the Hippocratic art above the narrow sphere of a mere bread-earning craft." The philosophic Feuchtersleben, in the preface to his most admirable "Medical Psychology," p. 9, remarks: "Body and mind are most intimately blended in every part of the structure of the living individual; and as the disorders of the mind are often removed by pharmaceutical remedies, so, on the other hand, the diseases of the body as frequently require the aid of the psychological physician. In disorders of the nerve especially, the physician can often effect nothing, if he do not in the first place direct his treatment to the mind. The numerous varying symptoms which, under the name of spasms, act so conspicuous a part in pathology, and unhappily a still more conspicuous part in real life, are often removed most suc-

cessfully and effectually by judiciously directing, controlling, and taking advantage of the state of mind; and, how few disorders are there of any organic system in which the nerves do not, at least sympathetically, suffer! We see, therefore, how extensive is the application of psychical methods of cure throughout the whole domain of the art."

Now, if these views be correct, and if in reality we do find in our actual observation of disease (at the bed-side of our patients) such an intimate connection and reciprocal sympathy existing between mind and matter, how shall we implicitly and blindly surrender up our judgment and experience into the hands of men whose dogmata are the results of some bright and momentary inspiration, some meteor-like ray, the sudden coruscation of the study lamp, and not the patient observation of medical facts during a long series of years, or deductions carefully and elaborately drawn from them? From the pen or the lips of a Watson or a Latham, a Brodie or a Travers, we may and actually do hail with reverence and gratitude the carefully selected and well-digested results of a long life honourably and usefully spent in ministering to the indigent and friendless poor the aid of medical or surgical science; such men, from their prominent position in public life, and the rigid performance of their hospital duties, have an irresistible claim upon our attention. Not so, however, with some physiologists of the present day; these learned individuals, with a rare and happy gift (intuitive and instinctive, we presume) spring forth, Minerva-like, armed cap-à-pie, from the brain of their father Jove (some crack medical school or new university of modern Babylon), and forthwith commence an indiscriminate onslaught upon all time-honoured and experience-tested medical doctrines: their magic and professional *caduceus* (like Aaron's rod before Pharaoh in the land of Egypt) swallows up all the minor constellations, and they at once assume the dictatorial throne.

We hear every day of new and startling discoveries in medical science: cod-liver oil, glycerine, æther, chloroform, gun-cotton, medical galvanism, *et hoc genus omne*; and doubtless the morbid and prurient taste for novelties of the present restless and excitable age must be gratified in some way: but, for my

part, whilst the present unnatural and arbitrary distinctions between cerebral, spinal, and sympathetic systems of nerves, each having an action independent of, and beyond the cognisance or control of the rest, are upheld; whilst learned and indisputable authorities insist that the brain is the exclusive domain of the physical principle ("ψυχή or immortal soul"), and has no connection whatever with other parts of the human body; whilst the spinal cord is the exclusive seat of the *vis nervosa*, and the presiding Deity (*alma mater*) over all the convulsive and spasmodic disorders, having at the same time no connection or relation to the sensorial faculty; whilst the sympathetic is purely and solely the nerve of vegetative or organic life—an independent centre, and wholly unconnected with and beyond the control of the cerebral or spinal centres; whilst the heart is independent altogether of nervous energy, and will even maintain its accustomed action long after its removal from the animal body; whilst the contractility or irritability of muscular fibre is due to some *vis insita* or inherent property totally distinct from nervous agency; whilst "the reduction of the food in the stomach, by the solvent power of the gastric fluid, is a purely chemical operation, with which the person's system has nothing whatever to do;" whilst absorption, assimilation, the circulation of the blood, nutrition, secretion, respiration, reproduction, &c. &c.;—whilst all these important changes and vital actions, so necessary and indispensable to the animal economy, can take place in the living machine called man, without the immediate connection or aid of the nervous principle or energy (call it by any name you please), I cannot look forward to any comprehensive or systematic principle of therapeutics being adopted by the present race of learned practitioners. Whilst such novel and ingenious views of the animal economy are prevalent, and are even enunciated by the High Priests of our medical mysteries and solemnities, and from professional chairs and modern universities, can it be wondered at that general and country practitioners of the present day (like Guerilla chiefs in the famous Peninsular campaigns) should wage war against disease, each under his own special banner? One will (Sangrado-like) bleed his patients copiously, keep

them in bed, and dilute the fluids of the animal economy with barley-water, &c.; a second will clear out the porridge-pot (as an old country practitioner used to tell me) with emetics and drastic purgatives; some will try mesmerism; others hydropathy, &c. &c., just as the brize stings them. In fact, one cannot help congratulating the world of sick patients on the brilliant variety and "*embarras de richesses*" of remedial agents, which will henceforth be brought to bear upon them. Of course, where one part of the human frame is not dependent (so the physiologists would tell us) upon another; where vital actions take place without nervous energy; and where doubtless (on the same theory), blood has no reciprocal action on nerve—or, *vice versa*, nerve does not influence blood; but all the animal functions "are merely the result of some purely chemical operation;"—such being the case, there appears to me no necessity for fundamental principles of therapeutics; and we shall probably ere long be furnished with new theories of medicine, to accord strictly with the doctrines of modern physiology.

Belper, South Derbyshire,
April 1860.

ON THE TREATMENT OF TYPHUS BY THE
INTERNAL ADMINISTRATION OF ICE. BY
M. WAUNER.

THE following is the mode of employment of ice which has been practised by M. Wauner, in typhus, during the last three years:—The patient swallows, every minute or two, a particle of ice about the size of a sugar-plum: these, when dissolved, do not amount to more than a glass or a glass and a half of water each hour.

When the natural temperature of the body is restored, and notwithstanding that the patient acquires extreme distaste for the remedy (a sure sign of his amendment), its employment is continued from twelve to twenty-four hours longer, according to the severity of the case. To relieve headache, the forehead is occasionally sponged with ice-cold water. An ounce of ice-cold water is also administered every six hours. Every alternate night the patient is placed in a bath at 27° R., a little over 90° Feh.—*Chirurgie Rendus.*

* * * If similar success attend the use of ice under other hands, typhus must cease from among the registered causes of death. M. Wauner states that *all his cases were cured!* Were they all cases of typhus? x

**EXPERIMENTS
ON THE
POISONOUS PROPERTIES OF
LOBELIA INFLATA.**

BY MR. CURTIS AND DR. PEARSON,
of Maryland.

THESE experiments were performed for the purpose of corroborating the evidence given at the trial of John Wood, at the *Carlisle Summer Assizes of 1849*.—See *London Medical Journals* for August and September, 1849.

Fluid preparations of the drug were preferred for internal use, because more easily administered. The alcoholic tincture is evidently far more powerful than aqueous preparations: these last, however, were used in order that the alcohol might not interfere with the effects of the lobelia.

The strength of our fluid preparations is in each case estimated according to the quantity of the drug used in preparing it, which, in the aqueous preparations, was so large that all the active property of the drug could not possibly be taken up by the water; but large quantities were used, in order that the preparation might be as strong as possible, for we experienced great difficulty in administering it. The tincture, when evaporated to an extract, appears to lose a portion of its activity, an insoluble resin being formed.

The immediate cause of death in the case of Wilson, and in the different animals, appears to have been extreme congestion of the lungs; the symptoms and post-mortem appearances in each case led us to this conclusion. The severe inflammations in the different tissues would, there is little doubt, have ultimately caused death, provided the congestion had failed to do so.

Experiments on the Hedgehog.

CASE I.—40 minims of the official tincture (equal to 5 grains of lobelia) were given by mouth, June 9th, 1849, at 8h. 40m. P.M.: the respiration increased from 21 to 64 per minute, and afterwards declined in frequency. The energy and muscular strength continued greatly diminished at 3h. 30m. P.M. of the second day, when 3iij. (equal to gr. xxiii. of lobelia) were administered, and it died immediately. It is extremely probable that in this case the

first dose would ultimately have proved fatal.

Section.—Immediately after death. The mucous coat of the stomach intensely inflamed and corrugated, especially at the upper curvature: the small intestines greatly inflamed at the upper portion, but less so towards the lower bowels: congestion, however, pervaded the whole tube; inflammation of the mucous membrane of the bladder; kidneys congested; all the cavities of the heart filled with fluid black blood; lungs greatly engorged; brain and its membranes congested; the pulsation of the heart continued for a considerable period after the body was opened.

CASE II.—June 9th, 1849.—Administered by mouth at 7h. 30m. P.M. Tinct. Lobel. 3i.—gr. viiss. In half an hour the respiration increased to 73 per minute, and was very laboured. The animal continued in a very debilitated state until 4h. 30m. P.M. of the fourth day, when 3ii. of the saturated decoction were given, which (if water extracted all the active properties of the drug) should equal gr. xxx. of the powder; but this appeared to have little effect. At 9h. 30m. P.M. of the same day, therefore, Tinct. Lobel. 3i.—gr. viiss. were given, great care being taken to prevent choking, as, from its sudden effects in the last case, we thought it possible a portion of the liquid might have passed into the trachea. The animal, however, died in half an hour, and so quietly that it was difficult to say when it ceased to breathe, the heart continuing to beat feebly for some time after the respiration had apparently ceased.

Section 18 hours after death.—The mucous coat of the stomach intensely inflamed and corrugated; small intestines inflamed, especially the upper portion; large intestines healthy; liver greatly congested; gall-bladder full; urinary bladder enormously distended, slightly injected at the neck; lungs much gorged with blood; the cavities of the heart, especially the left ventricle, filled with black blood; the vessels of the brain slightly injected.

CASE III.—June 18th, 1849.—Administered Tinct. Lobel. 3iiij. = gr. xxiii. at 2h. 30m. P.M. Collapse rapidly came on, and the respiration increased from 16 to 31 per min. In one hour tremor of the limbs was very evident; and in three hours and a half it struggled as if

in severe pain. The respiration continued extremely languid until the morning of the fifth day, the flies having deposited their eggs in its mouth, when, appearing rather stronger, Tinct. Lobel. 3j.—gr. xv. were given, and it died almost immediately.

Section 24 hours after death.—The mucous coat of the stomach intensely inflamed and corrugated; small intestines inflamed throughout, but particularly so at the upper part; the vessels of the mesentery enormously distended, the external surface of both mesentery and intestines being intensely red; liver of a sooty tinge in places; gall-bladder empty; urinary bladder intensely inflamed, but not much distended; the cavities of the heart contained black blood; lungs much engorged, and their pleural surface discoloured in patches, as if from inflammation; trachea and bronchi much inflamed; injection of the brain and its membranes.

CASE IV.—June 18th, 1849.—Gave, at 3h. 30m. P.M., 3iv. of the saturated decoction, which should equal gr. xlv. of Lobelia. Collapse, with laborious breathing, came on rapidly; and in half an hour the respiration was 24 per minute. At 6h. 15m. P.M. of the same day it struggled as if in severe pain, and vomited a quantity of clear fluid: died about the fortieth hour.

Section made 14 hours after death.—Stomach slightly inflamed at the pyloric extremity; duodenum slightly inflamed; liver natural; gall bladder full; urinary bladder slightly injected; heart flabby, the right side containing black blood, the left side empty; lungs gorged with blood; brain, its membranes and choroïd plexus congested.

CASE V.—June 18th, 1849.—At 4h. 30m. P.M. administered 3ss. of decoction as an injection, which should equal gr. xlv. of Lobelia. Collapse gradually came on, and at 6h. 45m. P.M. the respiration was 46 per minute.

3rd day.—At 9h. P.M., the animal appearing vigorous, though the nose continued very dry, the same dose was repeated.

4th day.—At 11h. A.M. 3ss. of Infusion, which should equal 3j. of Lobelia; and at 5h. P.M. 3ij. of Infusion, with 3ij. Tincture, equalling together 3j. of Lobelia, were given by injection. In half an hour convulsive tremor of all the limbs came on.

5th day.—At 10h. A.M. the animal had partly recovered, when 3ss. of Infusion, equal to 3j. of Lobelia, was administered, but returned almost immediately with fæces: vomiting also took place. The dose was repeated at 7h. P.M., which caused free vomiting and collapse.

6th day.—At 10h. A.M. 3ss.—3j. was given, but immediately returned, when the dose was repeated, but without effect. 3ss. was administered at 8h. P.M.

7th day.—At 10h. A.M. 3ij. of Infusion, equal to 3ss. of Lobelia; and at 4h. P.M. 3ss. equal to 3j. were given by mouth; at 8h. 30m. P.M. 3ij. equal to gr. xlv. of Lobelia, were administered, and he died in a few minutes: probably, however, some of the fluid might get into the trachea.

Section 15 hours after death.—Stomach inflamed and corrugated, particularly at the pyloric orifice: duodenum inflamed: rectum intensely inflamed, and the other intestines much injected: the mucous coat of the bladder inflamed: the right side of the heart full of black blood; the left empty: lungs greatly congested: congestion of the brain and its membranes.

CASE VI.—June 19th, 1849.—Administered by mouth at 8h. 30m. P.M. 3j. of Saturated Decoction, equal to gr. xv. of Lobelia. In a short time the respiration became increased in frequency, and he vomited a clear fluid.

2nd day.—At 12h. M. it appeared less vigorous, when 3ss. of Decoction, equal to gr. viiss. was given, after which he again vomited a clear fluid. At 4h. 30m. P.M. 3ss. equal to viiss. grains; and at 9h. P.M. xl. minims of Decoction, equal to gr. x. were given, which produced no effect for fifteen minutes, when 3j. equal to gr. xv. more was given.

3rd day.—It appeared vigorous at 10h. 15m. A.M., when 3j. of Infusion, equal to gr. xv. was administered, but produced no effect. In half an hour 3ij. equal to gr. xxx. were given; and at 5h. P.M. the dose was repeated.

4th day.—At 10h. A.M. Infusion, 3ij. equal to gr. xxx. of Lobelia, were given, but vomited immediately, and it appeared shortly to recover from the effects of the dose. At 7h. P.M. Infusion 3ij. equal to gr. xxx. were administered, which caused immediate purging, and, in a short time, general tremors of the body.

5th day.—At 2h. P.M. the respiration

was 45 per minute, the animal lying on its side, in which position it continued until 1h. P.M. of the seventh day, when it died almost imperceptibly, the flies having deposited their eggs in its mouth during life.

Section made one hour after death.—The mucous membrane of the stomach very soft, intensely red, and in some degree corrugated, indicating decided and severe inflammation, which, in a less severe form, pervaded the whole mucous surface of the intestines, which contained a copious secretion of mucus: the peritoneal coat injected: bladder showed evident signs of inflammation: lungs collapsed, only slightly crepitant, congested: the heart continued to beat for more than an hour after death, its right cavity containing black blood, the left being empty: the brain and its membranes congested.

Experiments on Cats.

CASE VII.—June 25th, 1849.—In this case equal parts of Tincture and Saturated Infusion were given, of which a few drops were administered by mouth at 10h. 30m. A.M., which caused almost immediate vomiting, when \mathfrak{zss} . equal to \mathfrak{xlv} . grains, were injected per rectum, which in a few minutes caused violent vomiting, a portion of the injection being returned immediately; rigors, followed by lateral rocking of the body, continuing at short intervals of about half a minute until 12h. M. The injection was repeated at 3h. P.M., but was immediately returned.

2nd day.—At 10h. A.M. gave \mathfrak{xij} . equal to \mathfrak{xxiiss} . by mouth, but it was immediately returned. At 2h. 30m. P.M. \mathfrak{zss} . equal to gr. \mathfrak{xlv} . was injected into the stomach by means of a syringe and elastic catheter, and a similar dose per rectum; that by the mouth was immediately returned, as well as some of that given by rectum; at least \mathfrak{xij} . equal to gr. \mathfrak{xxss} ., however, must have been retained. In a very few minutes severe collapse came on, the respiration increasing to 88 per minute, and afterwards remaining at 44 per minute. Pupils dilated, the eyelids nearly closed, and the membrane of the eye stretched to its full extent over the eye. The rigors and rocking of the body returned more regularly than after the former dose, the animal making many feeble efforts to escape, but always falling from extreme weakness, giving us the idea

that she suffered from suffocation. The animal appearing rather stronger at 6h. P.M., \mathfrak{zss} . equal to gr. \mathfrak{xlv} . was given by mouth, and the same by rectum, which, being all retained, produced immediate collapse, the respiration in 15 minutes reaching 104 per minute, declining during the next half hour to 48: the pulsations of the heart too frequent to be counted; the rigors and rocking motions were absent, but there were continued twitchings of the ears after each administration: the respiration became gradually slower, and sometimes rather irregular, until 2h. A.M. of the third day, when it died: the whole body was very cold at 9h. P.M.

Section made nine hours after death.—On opening the abdomen, the vessels of the portal system appeared greatly distended: the mucous membrane of the stomach much congested, of a slight rose colour, and filled with a light green fluid, having a slight odour of alcohol: the small intestines contained a large quantity of *fæculent* mucus of a deep green tinge, the mucous membrane being of a deep rose tint, and much injected: the large intestines loaded with *fæces*, much injected at the *cæcum*, but becoming less so towards the anus: the bladder much injected at the neck, the vessels being distinctly arborescent: the other organs of the abdomen healthy: the heart flabby, as if it had undergone distension, the right cavity containing a small quantity of fluid blood, the left being empty: the lungs, collapsed to a great degree, slightly crepitant, containing much blood, and a large portion of the upper lobe of the right lung discoloured, as if from extravasation: the blood in this, as in all the preceding cases, was fluid.

CASE VIII.—July 2nd, 1849.—This animal was suffering from disease of the skin, about six months old, but small and thrivelless in appearance. Administered at 11h. A.M. Infusion, \mathfrak{zj} ., equal to gr. \mathfrak{xv} ., which caused vomiting in the course of four minutes, the respiration increasing in a short time to 44 per minute: after the vomiting had ceased, another \mathfrak{zj} . equal to gr. \mathfrak{xv} . was given, which was also vomited, and caused purging. The dose was repeated before 1h. P.M. and retained: at 2h. P.M. the animal showed some signs of debility, the membrane being expanded over the eyes, when the same dose was again given, and retained: evident prostration

came on, a little urine being voided, but with evident pain and difficulty. At 3 P.M. a rocking motion was observed in paroxysms of three minutes' duration, with very short intervals, the impulse being antero-posterior in direction. At 9h. P.M., the collapse not being quite so great—though she still seemed in extreme pain—she took a little milk: the tremors, however, still continued.

2nd day.—The animal appearing to have partly recovered from the effects of the former doses, at 11h. A.M. 3ij. equal to gr. xxx. were administered and retained. For some time there was little appearance of suffering; but at 4 P.M. she was suffering from rigors and rocking motions, the direction being lateral, and almost incessant. At 5h. 30m. P.M. was lying on its side, and breathing very slowly: died at 9h. 30m. P.M., 34½ hours after the first dose.

Remarks.—In this case the animal took into its stomach a quantity of infusion which should equal about 90 grains; but most of this was returned by vomiting.

Section 13 hours after death.—The vessels of the mesentery gorged with blood; the peritoneal surface of the intestines rose-coloured and streaked with vessels; the exterior of the stomach of a pale rose colour; the interior slightly corrugated; the mucous membrane inflamed throughout, and of a rose tint, especially at the smaller curvature, and about the pylorus; the intestines inflamed, especially the ilium, which, with the jejunum, contained a considerable quantity of black blood; the ilium also contained a vast quantity of jointed worms; colon inflamed, but no appearance of blood; the vessels of the rectum very large, and gorged with blood, the bowel containing a large quantity of mucus; the liver pale in places, and much injected, in others showing signs also of extravasation; substance of the kidneys pale, but their vessels injected; bladder nearly empty, its mucous membrane inflamed throughout, but particularly at the neck; the pericardium contained a large quantity of serum; the right side of the heart containing a small quantity of blood, the left being empty; the lungs gorged with blood, and containing soft nodules, but whether tubercle or not, doubtful; the vessels of the brain nearly empty, its structure natural.

Remarks.—This animal had evidently

been suffering from previous disease; therefore the results are not so valuable.

CASE IX.—July 9th, 1849.—Six grs. of extract were carefully prepared by evaporating 3j. of Official Tincture of Lobelia by a gentle heat; this was mixed with Mucilage and inserted under the skin of the back at 10h. P.M. At 11h. P.M. had vomited, and appeared less spirited.

2nd day.—11h. A.M.: continues much the same, having voided ordinary faeces during the night; took a little milk.

3rd day.—6h. P.M.: appeared to have quite recovered from the effects of the drug; therefore 10 grains, prepared as the former, were inserted in another place under the skin of the back: this caused severe vomiting in fifteen minutes, preceded and followed by rapid pantings, with the tongue protruded as in the dog. In half an hour the respirations were 88 per minute; and at 6h. 38m. P.M. the membrane almost covered the eyes. At 7h. 10m. P.M. there was free vomiting, followed by almost constant tremors. At 7h. 30m. P.M. the membrane continued over the eyes, but she made vigorous efforts to escape, and a large portion of the poison exuded from the wound.

5th day.—She appeared to have quite recovered from the effects of the previous doses at 4h. P.M., when 3ij. of Infusion, equal to gr. xlviii. of Lobelia, were given by mouth: this caused immediate purging, and was vomited in a few minutes; therefore the dose was repeated at 6h. 35m. P.M., but was again vomited in half an hour. At 7h. 35m. P.M. 3j. of Infusion, equal to gr. vi. was given; tremors came on in fifteen minutes: in half an hour 3j. equal to gr. vi. was administered by rectum, which produced a powerful effect: in half an hour after the last dose, another ounce, equal to gr. vi. was given by mouth.

6th day.—Gave 3j. equal to gr. vi. by mouth, and the same by rectum at 1h. A.M.; voided urine copiously in a few minutes; was very weakly at 11h. 30m. A.M., and evidently still suffering from the effects of the last doses, when the injection was repeated. At 12h. 15m. P.M. the respirations were 128 per minute: it died at 1h. 30m. P.M.

Section.—The mucous membrane of the stomach rose-coloured, corrugated, and softened; duodenum ecchymosed in patches; other portions of the small

intestines slightly so; rectum corrugated, and of a deep rose colour; bladder healthy; the right cavity of the heart containing a quantity of black blood slightly coagulated, the left side empty; lungs greatly engorged; brain healthy; pus in small quantity, had formed in the wounds of the back.

CASE X.—July 11, 1849.—*Experiments with Injections alone.*—At 12h. M. administered ʒij. of Syrupy Extract of Lobelia, prepared from the Official Tincture: vomiting came on within twenty minutes; tremors within half an hour; she vomited at intervals till 12h. 35m. P.M.; ʒijss. were then given: vomited in 11 minutes; a very small quantity of faeces was passed during vomiting: at 1h. 40m. P.M. appeared in very great pain, and passed what appeared to be a little urine.

2nd day.—4h. P.M.: had apparently quite recovered: a quantity of Syrupy Extract, prepared with the Spt. Vin. Rect., was now given: passed a quantity of urine in five minutes; vomited moderately within seven minutes; in twenty-three minutes tremors came on; nearly all the injection was voided within half an hour. At 5h. 15m. P.M. tremors, severe and continued: at 6h. 40m. P.M. gave ʒij; at 7h. 30. ʒj.: at 11h. 45m. P.M. the animal being in great pain, and to all appearance dying, we gave ʒij. in order to destroy it, the pulsation of the heart being at least 140: she extended her paw as if in search of something, and continued to do so until 1h. A.M. of the third day: the eyes were closed.

6th day.—At 12h. 5m. P.M. appeared quite strong: ʒj. of Infusion, equalling gr. xii., was given, and all voided in seven minutes; in four minutes had begun to breathe rapidly; in twelve minutes vomited. At 12h. 24m. dose repeated; also at 2h. 42m. P.M., both being returned before 4h. 20m. P.M.: she then suffered from pain, with tremors. At 4h. 35m. P.M. dose repeated: at 7h. 5m. P.M. tremors continue, with cries; dose repeated: at 7h. 20m. P.M. discharged urine copiously, as also after a former dose. At this time the symptoms were increased: at 7h. 47m. P.M. a large portion was voided; dose repeated: at 10h. P.M. dose repeated.

7th day.—At 3h. P.M. had become strong again; dose repeated; in seven minutes vomited. At 3h. 15m. P.M. dose repeated; passed urine at 4h. P.M.:

at 4h. 20m. P.M. dose repeated: at 5h. 3m. P.M. dose repeated.

Remarks.—All the injections were voided almost as soon as given. To relieve the animal from torture, we gave prussic acid, which caused instant convulsions and death.

NOTE ON DR. DAVY'S OBSERVATIONS ON
THE AMOUNT OF
CARBONIC ACID EXPIRED IN
CHOLERA, AND ON ANIMAL
PUTREFACTION.

By WM. FRED. BARLOW, M.R.C.S.

In my paper on the condition of the body after death from cholera, I have spoken of the defective formation of carbonic acid during the cold stage of that disease, and of the question of putrefaction being in any way connected with the rise of temperature which is reported to have happened in the dead.

Dr. Davy observes, in a very kind letter with which I have been favoured by him:—"In 1818, when I first witnessed cholera in Ceylon, I noticed the muscular contractions after death from that disease, and also, during life, the diminished proportion of carbonic acid formed in respiration. The muscular contractions were first noticed in Ceylon, if I recollect rightly, by an able and esteemed friend, now no more, Assistant-Surgeon Finlayson. I believe they may be found in the Medical Reports, at the office of the Director-General of the Army Medical Department, in St. James's Place.

"In the second volume of my 'Researches' there are some observations on the putrefaction of animal matter, proving that the process is attended with increase of temperature and the formation of carbonic acid, most remarkable in the instances of the fibrin of the blood and muscular fibre exposed to the air—vide vol. ii. p. 343. I refer you to them, seeing that you mention in one of your papers Dr. Taylor's negative results."

Dr. Davy says further, in another and subsequent communication:—"Since receiving your note of yesterday's date, I have referred to a copy which I happen to have of my letter on cholera, as I observed it in Ceylon thirty-one years ago. From this I find that in all the

trials of the air expired, the proportion of carbonic acid was very much less than in health; that the venous blood was unusually dark, and little disposed to coagulate; and that there was little difference in colour between the venous and arterial blood."

I find that Sir Gilbert Blane has, in the eleventh volume of the *Medico-Chirurgical Transactions*, alluded with commendation to the observations of Dr. Davy and Mr. Finlayson, and given some account of their results. The cases which I extracted from one of Dr. Elliotson's lectures were noted and described by the latter gentleman; and it is the more necessary to state this, on account of their having been extremely well marked, very carefully observed, and clearly described.

The experiments of Dr. Davy on the expired air, showing the deficient quantity of carbonic acid it contained, are of no little interest. When one reflects on the state of the circulation in the collapse of cholera, it seems *impossible* to discover how carbonic acid could be formed and heat maintained as usual; but no inference drawn from reasoning can be compared for value, in inquiries of this nature, to the issues of experiment. It can hardly be doubted that less carbonic acid is exhaled than usual in cases of severe shock where the surface is chilled, in the sinking state in general, and all cases in which the blood-current is considerably enfeebled or impeded.

The different results of Dr. Davy and Dr. Taylor are no doubt to be explained by differences in their experiments.* The *nature* of the putrefying part, the *time* of putrefaction, and the *degree* of exposure to the air, clearly affect the inquiry. It would appear from Dr. Davy's researches that heat was owing to the *formation of carbonic acid*; if so, the *immediate* cause of animal heat is the same in the *dead and putrefying* as in the *living* animal. Dr. Davy's conclusions do not appear to affect what I have ventured to say already, as to there being no evidence to show that the rise of temperature noticed to have happened after death by cholera is caused by its agency. This inquirer distinctly states that he never, in his *experiments*, noticed a considerable elevation of temperature

unless when *putrefaction was most active*. And as to long maintenance of heat, it must be observed of the Bristol case, that it was not until the body had "cooled" that signs of putrefaction appeared on the abdomen. It must be remarked, too, that the formation of carbonic acid in dead animal matter, *after* the commencement of putrefaction, is in nowise inconsistent with the view that carbonic acid may be formed in the dead *before* putrefaction commences, under some circumstances; and so explain a rise of heat. Dr. Davy observes (*Researches*, vol. ii. p. 367):—"In a former part of this work, 'On the Temperature of the Human Body after Death,' two instances are given of an extraordinary high degree of temperature observed in bodies which had been dead a short time, and in both of which the fibrin of the blood had disappeared, as it does in putrefying; and yet the bodies exhibited none of the usual signs of the putrid change having even sensibly commenced. I then concluded, in consequence, that the unusual temperature was not owing to putrefaction, or a post-mortem effect; and, reflecting on all the circumstances of these cases, and on the phenomena witnessed in my experiments on putrefaction, I am confirmed in that inference; and obliged to suppose that it either arose from the ordinary sources of animal heat being more energetic than usual, or from the cooling process being comparatively inefficient, or else to imagine some peculiar morbid change in the blood itself, on which, in common with the disappearance of the fibrin, the unusual temperature may have depended."

There are many other observations of our author in the able and elaborate paper "On the Agency of Atmospheric Air on Dead Animal Matter, and on the Putrefactive Process," which deserve the most careful attention.*

METROPOLITAN INTERMENTS ACT. APPOINTMENT OF DR. SOUTHWOOD SMITH. DR. T. SOUTHWOOD SMITH, who was the medical member of the General Board of Health during the period of the Orders in Council (as authorised by the Diseases Prevention Act), has been appointed the second paid member of the board, provided by the Metropolitan Interments Act.—*Observer*.

* Dr. Taylor merely confined himself, in his note to me, to a detail of the result of *particular* trials; and, I am quite sure, intended to convey no *general* inference.

MEDICAL GAZETTE.

FRIDAY, AUGUST 16, 1850.

THE case of ANN MERRITT, who was convicted in March last, at the Central Criminal Court, of the murder of her husband by poisoning him with arsenic, has been recently brought to public notice under somewhat peculiar circumstances. In a debate in the House of Commons on the abolition of the punishment of death, this case was referred to by Mr. BRIGHT as showing the danger of inflicting "an irrevocable punishment, which might depend upon testimony of the nature of a medical opinion, liable to dispute, and to much and unavoidable uncertainty." The honourable member stated that this woman was sentenced to death "on the opinion of a medical man who appears to have given a rash and unscientific opinion, and which was afterwards strongly contradicted by the opinions of others of the same profession. In that case the proof was at length so strong, not of her being innocent, but of her *not having been proved guilty*, that the sentence was very properly commuted."*

The "medical man" here referred to—Dr. LETHEBY, a Lecturer at the London Hospital—addressed to the editor of the *Times* a letter in reply, from which we make the following extracts:—

"Had the liberal member taken the trouble to make himself acquainted with all the facts of Ann Merritt's case, he would have discovered that my opinions *were founded on fact, and that my evidence was the expression of truth.*"

* Some well-written comments on Dr. Letheby's evidence in this case appeared in a letter from Mr. G. B. Wadsworth, published in the *MEDICAL GAZETTE* of August 2d, page 218. It is only due to Mr. Wadsworth to state that our attention has been more particularly called to this important case by his judicious and temperate remarks. We have not hesitated to incorporate some of his objections in our strictures on Dr. Letheby's evidence.

"I take leave to say that the opinions advanced by me have never been publicly contradicted since the grounds on which they rest were placed fully and fairly before my professional brethren."

"In point of fact, the more I think over this case the more I bring it into relation, not only with the results of my own experience, *which is not small*, but also with the published accounts of other cases,—the more fully am I convinced that my conclusions were founded on fact, and that my evidence was the expression of truth."*

In a letter subsequently addressed by Dr. Letheby to the same journal we find the following passage:—

"I am well aware of the fact that Sir Benjamin Brodie, Dr. Leeson, and Dr. Ure, were consulted either by the sheriffs or the under-sheriffs concerning my evidence in the case of Ann Merritt; and I believe that, while every one of those gentlemen admitted that the questions put to me by the judge placed me in a very unsatisfactory and unenviable position, they also entertained opinions somewhat adverse to mine: but on this head I beg to state, first, *that their opinions were founded on most imperfect data, viz., the mere conclusion*, and not the premises, involved in my evidence; and, secondly, that though these gentlemen, as well as Dr. Billing and Mr. Davis, are all deservedly considered to be among the most eminent in the medical profession, yet (excepting Dr. Leeson), from the special nature of their practice, *and a total inexperience in the action of this particular drug*, they were not among the best qualified to give an opinion upon the toxic effects of arsenic. And I say again, that since the facts of this case have been fairly put before the medical world, no one has ventured to question the solidity of my conclusions."

We pass over the very bad taste which this letter displays on the part of a junior member of the profession in thus writing of men who had attained a

* *Times*, July 15th.—The *italics* are our own.

high rank as chemists and physiologists before Dr. Letheby had even entered the profession.*

In commenting on the *medical evidence* in this case, it is not our intention to discuss the degree of criminality which attaches to the wretched woman, nor is it any part of our design to import into the discussion, the propriety or impropriety of retaining capital punishment for the crime of murder. The woman may have been guilty of the charge, and have deserved to suffer death according to the present state of the law: all this may be conceded; but the great and material question remains—Was the medical evidence given on this occasion erroneous, or was it, as the witness himself wishes us to believe, "*the expression of truth?*" In support of the former view, we have the *opinions* of Sir B. Brodie, Drs. Billing, Pereira, Ure, and Leeson; and in support of the latter, the *statement* of Dr. Letheby. The Secretary of State did not hesitate to decide between these two conflicting opinions, and the sen-

tence of death was not carried into execution. The woman's life has been spared solely, as it appears, in consequence of a mistake in the medical evidence: and here we must observe, that however guilty in a moral point of view, a person may be,—if the verdict of the jury be in any way influenced by erroneous medical evidence, there is fair ground for the commutation of a sentence. It would not be consistent with humanity, or the safe administration of the law, that life should be taken when the medical opinion which has led to a verdict of *Guilty* is unsound, and contrary to general experience.

The history of the case of Merritt is comprised in a few words:—

The man was in his usual health on the night of Wednesday, January 23. On the morning of the 24th he was seen at his own house at *eight o'clock* in the morning: he was then sick, and he ascribed the sickness to his tea. At a *quarter* after *eleven* one of these witnesses saw him eating some gruel: at *one* to a *quarter* past, deceased said he felt very sick and queer and that he should not be able to do his work. Between *five* and *six* in the evening the same witness saw him again: he was then ill in bed, and complained of sickness and cramp in his feet.

Another witness saw deceased at twenty minutes past *twelve* on the morning of the 24th: he was then sick and vomiting.

A third witness deposed that he was with deceased and his wife (the prisoner) at twenty minutes before eleven o'clock on the morning of the 24th. He saw Mrs. Merritt pour out something into a basin, which he supposed to be gruel: she appeared to be mixing up a basin of gruel. The deceased took none of it then.

A woman named Gillett, who lived next

* We need hardly say that Sir BENJAMIN BRODIE's reputation as a physiologist and surgeon, and as a practitioner of forty-two years' standing in the metropolis, fully justified a reference of the medical facts of Ann Merritt's case to him. Some of his earliest contributions to science were on the absorption and action of poisons. Dr. BILLING is a scientific physician of high repute, who was long senior physician to the hospital in which Dr. Letheby is now a junior lecturer. Dr. BILLING delivered lectures there nearly thirty years since. Of Dr. URE and Dr. LEESON, as scientific chemists, we need not speak: their capacity for judging of the correctness of chemical evidence in a question of toxicology cannot be disputed. Rumour states that there is another individual who agreed with these distinguished men in condemning Dr. Letheby's evidence as unsound—namely, Dr. PEREIRA; but probably Dr. Letheby was not aware of this fact, or he would have been more guarded in setting up his own judgment against that of Sir Benjamin Brodie and Drs. Billing, Ure, and Leeson.

On referring to the Medical Directory, we find Dr. Letheby's qualifications to be a Bachelor of Medicine in the University of London, of *seven* years' standing, and a Licentiate of the Apothecaries' Society, his license dating from 1838. It appears that he is neither a Member of the College of Surgeons nor of the College of Physicians, and has only the half qualification of the University of London; yet he talks of the "*total inexperience*" of such men as Sir B. Brodie, Drs. Billing and Ure, on the action of arsenic, &c. &c.

* In order that Dr. Letheby may have no reason to complain of the source whence we derive our information, we have procured the Sessions Paper of the Central Criminal Court, March 1850, in which the minutes of evidence were taken in an authentic form by short-hand writers, and published under the superintendence of the city authorities.

door, was called by the prisoner at *half-past eight* o'clock on the morning of the 24th. The prisoner told her her husband was *very sick*, and had the bile. Deceased was seen by this witness between *ten and eleven* o'clock: he seemed to be ill. The prisoner was emptying some thick gruel out of a saucepan into a basin, and pouring some water to it. The gruel was made of oatmeal, fetched by a son of the witness's from the corn-chandler's at Mrs. Merritt's request. This was shortly after deceased came home ill. The prisoner gave as a reason for preparing it, that the deceased was *very thirsty*. This witness saw no more of either of them until *ten minutes past nine* at night, when Mrs. Merritt came for her. She found the deceased in bed retching violently, complaining of a burning pain in his chest, and a violent pain in his stomach. The witness remained at the house until *half-past twelve o'clock* at night, when deceased died,—herself and the prisoner being the only persons present at the time.

As the prisoner's guilt is not the question which we propose to discuss, we may merely observe that she made various statements which tended to show a guilty knowledge of the cause of her husband's illness. Among other circumstances adduced in support of the charge, it was proved that she had shown great eagerness to procure money from a burial-club to which her husband was a subscriber. She denied having possession of poison; but it was shown that on the 19th of January, only five days before her husband's death, she had purchased two separate pennyworths of arsenic at a druggist's shop. She said it was to poison some mice. The druggist put the arsenic in two packets of *white* paper, the quantity of arsenic in each packet being half an ounce. They were labelled *Poison*. When asked to account for the disposal of the arsenic thus traced to her possession, she said she placed it in a cupboard where her husband kept his soda

and acid powders, which he was in the habit of taking in the morning; "that she emptied the powder out of the paper with the word '*Poison*' upon it, and destroyed that paper; she screwed the poison up in another piece of paper, and left it in the cupboard; and, if he had taken the poison, he must have taken it in a mistake; that she afterwards destroyed the whole of the powders that were in the cupboard, and put them in the fire; she said she bought it (the arsenic) in a pet, and she intended to take it herself if her husband had gone on in the way he was going on."

We now come to the *medical evidence* in support of the charge. The first witness called was Mr. Toulmin, a highly respectable practitioner at Clapton. He deposed

that he was sent for between *half-past ten and eleven* o'clock on Thursday night, 24th January. He found deceased in bed, complaining greatly of pain in his stomach and cramps in his legs: he was sick. His pulse was very low, and his skin below the natural temperature. On Friday morning he saw him dead. The prisoner objected to a post-mortem examination; but this was made on the 28th, under the order of the coroner, by witness and Mr. Weloh, a surgeon in the neighbourhood. The stomach, with its contents, was removed from the abdomen. When opened, it contained *a thickish matter slightly pink*.* This was poured into a stoppered bottle. On the coats of the stomach there were red spots, such as are observed in persons who have died of an irritant poison. The stomach and contents were delivered to the assistant of Dr. Letheby, at the London Hospital.

* In a letter addressed by Dr. Letheby to the Editor of the *Medical Times* of March 23d, it is stated that Mr. Toulmin found, on inspection, "*three-quarters of a pint of undigested gruel in the stomach*." Mr. Toulmin, in his evidence, makes no such statement. He neither speaks of the quantity found, nor of the contents consisting of undigested gruel. This is Dr. Letheby's version of Mr. Toulmin's evidence. Yet, in his correspondence with the *Times* newspaper, Dr. L. refers to this letter as placing the facts "fully and fairly" before his professional brethren!

The next medical witness was Dr Letheby. As the evidence of this gentleman has been so seriously impugned, it is only fair to give it verbatim from the Sessions Paper:—

DR. HENRY LETHEBY: I am a bachelor of medicine and professor of chemistry at the London Hospital. On the 29th Jan. I received from Mr. Long a glass bottle and earthen jar—I entered on an analysis of their contents—I experimented on the contents of the bottle first, and detected *eight grains and a half of white arsenic*—by one course of experiments I reproduced the arsenic in a metallic form—it is in this tube (*produced*)—the earthen jar contained part of a human stomach—I noticed a peculiar appearance in it, which I have noticed in cases of poisoning by arsenic—there was a very small portion of a *whitish powder adhering to the inner lining of the stomach*, too small a quantity to ascertain what it consisted of—I then examined the intestines that were in the jar—I subjected them to a chemical analysis—the result was the detection of a very small quantity of arsenic—there was also in the jar part of a human liver—I subjected about a quarter of a pound of it to experiment—I say that, that you may form a judgment of the quantity in the entire liver), and obtained a quantity of metallic arsenic (*produced*)—it was *too minute a quantity to weigh*—that in the stomach was the only quantity I weighed—that would be quite sufficient to produce death—I had an opportunity of witnessing a case where two grains and a half killed—the general quantity would be eight grains—I look upon that as an average dose—it would generally be fatal—vomiting is almost invariably the consequence of arsenic introduced into the stomach—a person attacked in that way would be likely to throw up a portion of the arsenic—looking at the quantity I found, and the parts I found it in, in my judgment *the arsenic I found had been taken not more than two or three hours before death*, but that is a matter of opinion: a dose might have been given before—it would depend on many circum-

stances how soon it would find its way to the liver. .

Cross-examined.—Q. About five grains of arsenic, you say, would cause death; do you mean taken together? A. Yes, or less; $2\frac{1}{2}$ grains have done so—I know nothing of this transaction but from the examination—I found a very small portion in the liver, perhaps about 1-10th of a grain in a quarter of a pound of liver—a liver weighs about 5lbs. on an average—supposing it was equally diffused, there would be twenty times that quantity; that would be two grains—*my observation is reference to the time it had been taken, has reference both to the stomach and liver.*

Q. Are the data at all safe? A. Yes, I will tell you why: I found in the stomach $8\frac{1}{2}$ grains of arsenic, and there was not much in the intestines; I conclude, therefore, *that there had not been time for it to have passed into the intestines, which would have been the case if it had been taken a long time before death; but there was only a trace in the intestines, so I conclude that it was a very short time before death*—that furnishes datum to me to form a judgment on the subject of hours—food remains in the stomach five hours before it passes into the intestines—I am able to say that the contents of the stomach pass into the intestines within four, eight, or ten hours—from experiments which have been performed on living subjects, *I have not the least doubt*—I saw the intestines; they were in the jar; they did not appear to be influenced by arsenic; they were slightly red, and there were traces of arsenic; I have reduced something that was in the intestines into a metallic state—I experimented upon it, and found it was arsenic—it was destroyed in the experiment—I was obliged to submit it to experiment to prove it was arsenic—it is not likely I should find arsenic in the liver without some being in the intestines—the time would not depend on the constitution of the person—digestion depends on the constitution, but I am speaking of the average—digestion is more or less rapid, according to the constitution of the person who has received the subject matter—I have heard of cases

in which matters which would not digest have remained three or four days, but those were solid matters—I think liquids pass into the stomach (intestines?) under all circumstances within five hours, as (after?) they are imbibed—there is a valve which prevents solid matters from passing into the stomach till they are digested—the arsenic was in a liquid state; all except a little white powder on the side of the stomach—I am obliged to have recourse to an average to form an opinion as to how long it would take—we have no means of dealing with an independent case, but by the average.

MR. BODKIN.—Q. What did the contents of the stomach look like. A. Thick gruel; they were filtered, and I examined the filtered portion—my opinion is that the arsenic had been taken two or three hours.

Our readers will now perceive that the main question at this trial was not whether the man died from arsenic, or any other cause, but *At what time was the poison taken?* If taken on the morning of the 24th, then there was a remote possibility that such a mistake as that suggested by the prisoner might have been made; or that the poison, might by some accident, have entered the deceased's body at breakfast. If Dr. Letheby's evidence, however, were, as he alleges, "the expression of truth," then it follows that the arsenic must have entered the man's stomach only *two or three hours before death*,—i. e. from half-past nine to half-past ten o'clock at night, his death having taken place at half-past twelve. If any doubt could exist as to the meaning of Dr. Letheby's opinion, he has entirely removed it by publishing a letter in the *Times* of July 15th, in which he says—"Now if we were to found our judgment on actual general occurrences, instead of assumed special instances, we cannot, I think, but conclude, as I did, that the poison and gruel found in Merritt's stomach after death had been administered to him *subsequent to his going to bed, and within four hours of*

his decease." It will be observed that Dr. Letheby here adds another hour; but it will be seen that, in his statement at the Central Criminal Court, which alone could influence the jury in their verdict, he most positively limited the time to *two or three hours*.*

Fortunately for the prisoner, it happened that a medical practitioner of some experience was accidentally in Court, and heard with surprise this extraordinary piece of medical evidence. After the conviction of the prisoner, this gentleman, as we are informed, communicated his suspicion of the unsoundness of the medical opinion to the proper authorities; and, as we have said, it was condemned as incorrect by Sir B. Brodie, Dr. Leeson, Dr. Billing, and others: and the woman was consequently reprieved.

As the prisoner was attending on the deceased at the time so positively assigned by Dr. Letheby for the "*administering*" of the poison, and there was no suspicion of suicide, it followed, if his view was correct, that the prisoner must have given the arsenic to him. All possibility of mistake or accident was entirely removed by an asseveration so solemnly made.

Our readers who have had any experience in cases of poisoning with arsenic, must be well aware that, as a general rule, it is not possible, from the examination of the stomach and its contents, to assign *the period at which the poison was taken*. In general, the occurrence of symptoms, and the history of their progress, are looked to; but Dr. Letheby has adopted the novel

* In the so-called explanatory letter of March 23d, addressed to the Editor of the *Medical Times*, the same liberty is taken with the period assigned for the ingestion of the poison. "I concluded," says Dr. Letheby, "that the matters in question (undigested gruel and arsenic) had not been in Merritt's stomach for more than *four hours* before death." This difference of time is very material; and it is wholly concealed from the editor and readers of that journal, that the time sworn to at the Central Criminal Court was *not more than two or three hours*!

plan of basing his opinion on the comparative insolubility of arsenic in organic liquids, and on the time required for the digestion of gruel in a *healthy* stomach containing no arsenic!

There are two orders of circumstances by which the correctness of an opinion carrying with it such weighty results to an accused person, may be tested:—1, the evidence of facts deposed to by non-medical witnesses unacquainted with scientific theories; 2, the consistency of the opinion itself with general medical experience.

Dr. Letheby's opinion on this occasion is inconsistent, not merely with the facts proved in the case, but with all medical experience. He substantially told the Court that the arsenic which he found in the stomach was administered to the man not earlier than from half-past nine to half-past ten o'clock on the night of his death. The general evidence shows that at *ten minutes past nine* the woman Gillett was called by the prisoner to her husband. This woman went in to the deceased, and found him then retching violently, and complaining of a burning pain in his abdomen. From half-past ten to eleven o'clock he was seen by Mr. Toulmin, the surgeon; and the symptoms caused by arsenic, were then well developed. Indeed, the whole of the evidence tends to show that the poison was taken by the deceased shortly before eight o'clock on the morning of the day on which he died. No other theory will account for the symptoms under which he laboured throughout the day. His entire illness lasted about seventeen hours: the presence of the usual symptoms of irritation caused by arsenic were deposed to by various non-medical witnesses, and there is no evidence to show that the man had taken any poison subsequently to the time at which he was first attacked in the morning. Dr. Letheby's opinion involves the gross

improbability that *twenty minutes before* the prisoner "administered" the eight grains of arsenic found in the deceased's stomach, she fetched the witness Gillett; and that in the presence of this witness, and of Mr. Toulmin, the dose of arsenic, dissolved in gruel, was administered by her to her husband! The evidence, however, plainly shows that the man was in a hopeless condition, and actually dying, from the effects of the poison some time before the *earliest period* assigned by Dr. Letheby for its administration!

This unguarded statement, however, is not more at variance with the circumstances of the case than it is with medical experience. As facts justifying his opinion, Dr. Letheby relies on the allegation that the arsenic was *not in a solid state* in the gruel,* but in a *state of solution*. He says, further, that the quantity of gruel amounted to three-quarters of a pint (sixteen ounces), and that the arsenic dissolved in it weighed eight and a half grains. We pass over the great difficulty which must necessarily exist in determining whether so small a quantity of arsenic was actually dissolved, or, as Mr. Wadsworth suggests, mechanically diffused through so large a quantity of a liquid, described by Mr. Toulmin as a "thickish matter, rather pink;" for it is in practice scarcely possible to arrive at a safe conclusion on this point when, as in Merritt's case, the quantity of arsenic is only *half a grain to one ounce* of "thickish matter." Admitting, however, that the arsenic was *dissolved*, excepting the "little white powder" which adhered to the stomach, and the nature of which was not determined by the witness,† we

* See letter in *Medical Times*, March 23, page 237.

† This was a very serious omission, as the witness made so great a point against the prisoner, that the white arsenic was *not in a solid state*, but in a state of solution. Any quantity of white powder which could be seen adhering to the stomach could have been easily tested for arsenic. If proved to have been arsenic, the inference

cannot perceive how this shows that the arsenic had not been taken "more than two or three hours before death." If a person swallows a large quantity of tea or gruel some hours after having taken arsenic, it is by no means unusual to find a portion of the poison dissolved in this liquid. The powder hanging about the stomach becomes more or less dissolved by all liquids which enter the organ, especially if they remain in it for two or three hours, or longer. The witness assumes that vomiting would have removed it: but vomiting may remove a part, although not the *whole* of the poison; and the solution of arsenic in the gruel might have gone on until death, or even until the body was examined, *i. e.* three days afterwards.* It would be preposterous to assume, in a case like this, that because the arsenic was dissolved in the gruel it was therefore given with it† only a few hours

from *entire solubility* of the poison in the contents would have been, of course, subverted. Dr. Letheby, in his letter to the *Medical Times* justifying his opinion, does not even give the wretched woman the benefit of the doubt, to which she was clearly entitled, that the small quantity of whitish powder adhering to the stomach, and not analysed by him, was really a portion of arsenic undissolved!

* We must here again call the attention of our contemporary, the Editor of the *Medical Times*, to the very incorrect version of facts which his journal has been allowed to circulate under the designation of a full and fair statement. Dr. Letheby represents the question thus:—"Is it probable that a dose of arsenic taken early in the morning would have remained in the stomach for upwards of sixteen hours, in spite of the incessant vomiting, drenching with tea, &c.?" Mr. Wadsworth has justly remarked that this question is quite irrelevant, and has no bearing whatever on the case. If Dr. L. was prepared to swear that the deceased had taken no more arsenic than was found in his stomach after death (eight grains), there might be something in the argument; but there can be no doubt that the deceased actually swallowed a much larger quantity, and that only a small part of the "dose" so taken remained in the stomach, the rest having been removed by the vomiting (there is no evidence of *incessant* vomiting, drenching with tea, &c.).

† We have met with a case in which arsenic was swallowed in powder at one dose, and death took place in nineteen hours after abundant vomiting and purging. In the stomach there were twenty ounces of a bloody liquid, holding dissolved (as it was supposed), five grains of arsenic. No portion of the poison was found in powder. It might just as reasonably have been inferred, in this case, that the few grains of arsenic had been given in the *bloody matter*, as a vehicle, two or three hours before death; be-

fore death. All the medical facts in Merritt's case are consistent with the assumption that only *one dose* of poison was taken in the morning, and that none was given subsequently. The man no doubt swallowed a large dose, and the fact that a small quantity of the poison was found dissolved in sixteen ounces of gruel is certainly not adverse to this view of the case; but whether this assumption be adopted or not, we hold that the fact of solution affords not the slightest support to the opinion so strongly expressed by Dr. Letheby at the trial. The gruel, according to the witness, was found *undigested* in the stomach: hence he infers that, as gruel is digested in three or four hours in a healthy stomach, it could not have been longer than that time in the stomach in this instance. Dr. Letheby therefore assumes that gruel is just as readily digested in a stomach violently affected by arsenic, as in one that is perfectly healthy! We altogether doubt the correctness of this conclusion, and believe, from the evidence, that the gruel may have been there four, seven, eight hours, or even longer. The period required for the digestion of food in a stomach poisoned with arsenic has not yet been determined; and we doubt, even Dr. Letheby's experience, which he tells the Editor of the *Times* "is not small," can help us to a solution of this question. The witness's opinion respecting the shortness of the period during which the poison had been in the body, was, he states, further strengthened by the *small quantity* of arsenic (a mere trace) present in the *intestines* compared with the quantity (eight grs.) found in the stomach. In cross-examination, he said that there had not been time for it (the poison) to have passed into the intestines.* Is it pos-

cause, as there had been active vomiting throughout the day, this might have been supposed adequate to remove the *whole* of the arsenic.

* This is quite adverse to the previous statement, that "a dose might have been given be-

sible to produce from the annals of forensic medicine a statement more reckless or more dangerous in its consequences than this? If we find a smaller quantity of arsenic in the intestines than in the stomach, it is, upon this view, to be affirmed that it has *not had time* to pass from the stomach into the bowels; and, therefore, that it must have been introduced in the former organ but a very short time before death! It does not appear to have entered into the witness's thoughts that there were no means of determining in this instance how much had been already expelled by vomiting and purging, and that the smaller quantity found in the intestines might have been owing to that which had been taken some hours previously, having been drained away by purging. The witness first constructs a theory that the arsenic could not have been in the stomach more than two or three hours, and then makes every other medical fact bend to this. Cases are by no means unfrequent in which the larger portion of the poison is found in the stomach, while a small quantity (only a trace) is found in the intestines. The exact distribution of the poison by vomiting, purging, and the ingestion of solid or liquid articles of food, is so much a matter of accident that no person possessed of sound experience on poisons, would venture upon so loose an inference from the relative proportion found in the stomach or bowels!

But we are told that arsenic was found in the *liver* in the proportion of about the 1:10th of a grain in a quarter of a pound; making, therefore, by calculation, about *two grains* of the poison in the whole of the organ. We have then the extraordinary assertion that

the witness's observation in reference to the *time* the poison had been taken, had reference both to the stomach and *liver*: and, when asked whether the data were *safe*, he replied,—Yes. Dr. Letheby must, we think, have presumed greatly upon the ignorance of those whom he was addressing at the Central Criminal Court, to assert that the detection of *two grains* of arsenic in the liver was a confirmation of his view that the poison had *not* been more than two or three hours in the body! According to good experience, the fact of so large a quantity of arsenic being found in the liver would prove the very contrary.

As a certain period of time is required for the absorption and deposition of poisons, it is a reasonable inference that when one-fourth as much arsenic is found in the liver as in the stomach, the poison, in order to have become thus deposited, must have been in the body many hours,—sixteen or twelve at the least. Dr. Letheby, however, would have us believe that the *two grains* which he says he detected in the liver, were actually dissolved in gruel and administered to the deceased only two or three hours before he died! In how many livers of persons who have died from arsenic in two or three hours, has Dr. Letheby found so large a quantity of the poison as that here assigned? If he has met with this extensive deposition of arsenic in the liver in a single instance, where death has been caused by arsenic within this very short period of time, it is our opinion that he stands alone in his experience; if he has *not* met with such an instance, why did he recklessly swear to a speculation on which the capital conviction of an accused person probably rested? It is rare enough that death is caused by arsenic in so short a period as *five* hours; but from the complete confidence with which this deposition of the poison in the liver is stated to be a *proof* that it

fore;" because, with this admission, there would have been time for the poison to have passed into the bowels, and to have left more than a trace, supposing, as Dr. Letheby appears to assume, that when once there it ought to remain there.

could not have been in the body more than two or three hours, we can only presume that Dr. Letheby must have had the opportunity of examining the livers of many persons who have died from arsenic in *two or three hours*! Nothing short of this extensive experience would, in our view, have justified his answer,* or the very bold assertion that the data were perfectly *safe*.

We have now gone through the details of a very painful case. We do not grudge the space devoted to it, because we think that the question involved was one which, for the sake of public justice, demanded serious examination. Our readers will now be enabled to judge how far Dr. LETHEBY has been justified in charging such men as Sir Benjamin Brodie, and Drs. Billing and Ure, with "total inexperience" on the subject of poisoning with arsenic, merely because they disputed the correctness of the statements made by him at this trial. Let them now consider how far the conclusions of the witness were

* A case bearing on this question will be found in the 38th volume of the Medical Gazette, page 424. Dr. Geoghegan, of Dublin, who communicated the case to this journal, informs us that death took place in *seven hours*. The quantity of arsenic found in the liver was *two-fifths of a grain*, as nearly as could be approximately determined. In another case, in which death took place in *nine hours*, the quantity of arsenic in the liver was very small—too small to be weighed, or more than conjecturally estimated. The fact is,—these rapid cases of death from arsenic are so rare, as not to allow the question to be determined practically; and yet we have a positive statement stoutly sworn to, as if the premises on which it was based were susceptible of demonstration! Contrary to Dr. Letheby's rule, toxicologists generally consider that the detection of arsenic in the liver, especially in the large proportion of two grains, is a clear proof that the arsenic has *not* been taken a short time before death, but that it has been in the body *many hours*! In a case examined some years since by two eminent French toxicologists, MM. Bayard and Chevallier, they found arsenic in the tissues of the stomach and intestines, but not a trace in the liver. Their conclusion is in accordance with true experience—"qu'il est présumable que cette préparation arsenicale n'a été ingérée que peu d'heures avant la mort, puisque le foie n'en contenait aucune trace, et qu'il n'y a pas eu d'absorption par cet organe." (Annales d'Hygiène et de Médecine Légale, vol. xxxv. 1, 1846, page 149.) Dr. Letheby may, however, object to these gentlemen, as labouring, like Sir Benjamin Brodie and Dr. Billing, under "a total inexperience in the action of this particular drug!"

founded, as he alleges, on *fact*, and whether his evidence was really the *expression of truth* as it is interpreted by others. Dr. Letheby may have sincerely believed that what he swore to was true; but it is precisely this want of experience or judgment which rendered his testimony on this occasion unsafe. We do not hesitate to assert that every fact in this case is explicable on the supposition that the man took the arsenic in the morning, and died from its effects at night, after about seventeen hours' illness. There is no medical proof whatever that he had at any time more than *one* dose. There is certainly no valid reason for supposing that the prisoner gave him any arsenic within two or three hours of death; nor does it appear from any part of the evidence that the poison was taken in a dissolved form in gruel. Dr. Letheby has put a wrong interpretation upon the facts, and strained them in a way to suit his view, which no sound experience can justify. As a proof of this, we would only point to his theory regarding arsenic in the liver. According to MM. Chevallier, Bayard, and, we believe, all toxicologists, the fact observed by Dr. Letheby of the presence of two grains of arsenic in the liver would prove the very reverse of what he asserted at the trial. On a balance of probabilities it incontestably showed that the arsenic could *not* have been taken a short time before death.

We should have imagined that the time which had elapsed since the trial would have allowed Dr. Letheby to perceive the gross error of which he had been guilty, and which, under other circumstances, might possibly have consigned an innocent person to the scaffold. There was in this case a heavy weight of moral evidence against the prisoner; but Dr. Letheby's medical opinions were not, of course, based on this. Had the man swallowed the arsenic by mis-

take for an acid powder, in the morning, and had the woman been otherwise perfectly innocent,—here was a medical practitioner swearing in the most positive terms that the deceased must have had a dose of poison within two or three hours of death, when the wife alone was attending him, and when no other hand but hers could have administered the poison!

It appears from the letters recently published in the *Times*, that after five months Dr. Letheby persists in the correctness of opinions which we believe to be fraught with error most dangerous to all who happen to be accused of crime, and most damaging to the character of medical science. Six eminent professional men, of long and large experience, assure him that he is wrong; but he persists that he is right. His letters to the *Times* show that he sets public and professional opinion at defiance. Thus in the *Times* of only the 15th July, we find him asserting "that the opinions advanced by me have never been publicly contradicted since the grounds on which they rest were placed fully and fairly before my professional brethren."

After the complete failure of Sir B. Brodie, Dr. Billing, and others, we do not hope to convince Dr. Letheby that he is in error; but our object will be answered if we put him on his guard in future, or if we can succeed in teaching him that whatever his own experience may have been, he is bound, in a question affecting the life of a fellow-creature, to consult the experience of others. Had he done this with earnestness, he would have found on this occasion that the experience of others was decidedly adverse to his own. Our belief, however, is, that he was anxious to give a positive answer to every question, without, perhaps, at the time perceiving how far it was inconsistent with the facts of the case and with the doctrines of medical science.

The Secretary of State has, we believe, exercised a wise discretion in declining to order the execution of the woman Merritt, when it was highly probable that the opinions of the jury, in returning a verdict of *Guilty* against her, were influenced by unfounded medical statements regarding the time at which arsenic was taken by the deceased. If this woman were really guilty of murder, she owes her escape from capital punishment to the mistaken opinions of a medical witness. While it is far better that this should happen than that one who is innocent should be convicted and executed upon erroneous medical evidence, we cannot too strongly impress upon the minds of our readers, that no mistake of this kind can be made on a trial for a murder, without being attended with the danger either of leading to the acquittal of a guilty person, or to the conviction, and perhaps execution, of one who is innocent! All may learn from the facts of this remarkable case, that there are certain questions in Forensic medicine which cannot yet be solved by medical science. It is surely better at once to state this plainly, and say that the question proposed does not admit of an answer, than to make a jump in the dark and give a speculative opinion, in order to avoid the appearance of ignorance.*

* In the letter published at the commencement of this article, Dr. Letheby says that Sir B. Brodie, and others to whom the case was referred, admitted that the questions put to him by the judge "placed him in a very unsatisfactory and unenviable position." It is strange that Sir B. Brodie should have made such an admission. It was not the questions, but the answers, which placed the witness in an unsatisfactory position. If asked, When was the arsenic administered? the witness was not bound to reply that it had certainly not been taken more than two or three hours before death; he might either have referred the taking of the poison to an earlier period in the day, when symptoms of vomiting first came on, or he might have declared that he was not able to state at what period the poison was administered. The case would have then gone fairly before the jury.

Reviews.

Homœopathy and its Principles explained.

By JOHN EPPS, M.D. Published by the English Homœopathic Association. 8vo. pp. 320. London: Piper, and Baillière. 1850.

Dr. Epps begins this confession of his belief as to medical practice with a "brief reference to the treatment which Truth has, in all ages, experienced when first introduced to the notice of mankind." Thus—"The opposition," observes the author, "always created upon the discovery and the diffusion of any truth, has been proportioned in strength, intensity, and amount, to the interests which the truth, by the very necessity of its nature, either must, or appears likely to, overturn." The truth, as regards medical science, we are informed, *was pointed out by the finger of God, to the GENUISED* eye of Hahnemann*.† The pretension, however, to a divine revelation, is not new in these days! Because there are those among us who, after a laborious investigation of every branch of medical science, cannot discover in the *assumptions* of Hahnemannism the credentials of a divine development of truth, it is the practice of homœopaths to range them in the same category with the popish persecutors of Galileo, the opponents of Newton, the impugnors of Harvey, and the enemies of Jenner! Dr. Epps forgets that in having recourse to this line of argument he and his co-advocates of homœopathy have no stronger ground of offence or defence, than the advocates of chronothermalism, hygeian pills, or of any other system of quackery, no matter how monstrous its pretensions: one and all adopt the same line of argument as Dr. Epps, and which, we may observe, has no relation whatever to the subject under discussion. What interest, we would ask, has the medical profession beyond the cure of disease? Are not their studies, and is not their remuneration, directed to it and dependent thereon? Noble Lords, M.P.'s, M.D.'s, and other members of homœopathic associations, cannot be supposed to be wilfully ignorant or forgetful of the fact, patent to all the world besides,

that the members of the medical profession have ever been among the first and foremost of the movers of the most important, and most beneficial, social improvements. Therefore, all the records of "flames, faggots, tortures, racks, fiery furnaces," which are adduced as the lot of the adherents of *truth*, may be regarded as so many mere rhetorical flourishes, useful only to conceal the weakness of an argument.

What is Homœopathy?

Dr. Epps observes—"To make the answer to this question clear, and thus to demonstrate the truth of homœopathy, it will be necessary to notice some particulars in connection with *LIFE*; for it is to life in its modifications that homœopathy has relation."

"The particulars in connection with life," to which the author refers, are comprised in a verbose digression on the animal kingdom, vitality, health, &c., containing the most trite statements, familiar to schoolboys.

Then follows a picture of the practitioners of the "old system," consisting in a gross exaggeration of the defects of the "system," and a culpable suppression of its true merits,—a picture perhaps adapted to the tastes of homœopathic readers, who, however, it would appear, are not allowed to swallow abuse of rational medicine "in homœopathic doses."

It is not our intention to burden our pages with many quotations from this essay; but we will take, as specimens of the author's fairness or ignorance, the first case we find:—

"A sick person is sleepless. He prays for something to cause him to sleep. The wish is natural, and the physician ought to be able to aid him. The antipathic physician seeks to aid him by giving him an opiate. In doing so, he acts empirically without science." (p. 14.)

We need offer no comment on this exhibition of Dr. Epps's knowledge of the "old system."*

To return to the question—What is Homœopathy? Dr. Epps thus expresses its fundamental principle:—

"Inducing a medicinal disease, in symptoms similar to those presented in natural disease, will cure the natural disease."

Let us examine some of the *facts* that the author adduces.

* We are at a loss for the interpretation of this word: it doubtless has a homœopathic meaning!

† The italics are our own.

* A case recently reported in this journal (page 42), throws some light upon the mode in which homœopathic globules act to procure sleep.

"You knock yourself."

"You rub the part knocked,—that is, you use a succession of gentle but rapid knockings."

This is pure Lingism ! or Kinesipathy.

"You are palsied."

"You use strychnine, which produces palsy."

Does strychnine produce no other effect than palsy? If so, why not say so?

"You are frost-bitten."

"You rub with *snow*,—a result of frost, but you do not expose yourself to the identical frost again."

Is the above-named principle acted upon here?

"You have sore throat."

"Belladonna taken, which, according to Mr. Wade, produces swelling of the tonsils and inflammation of the palate."

What can be the value of such a *fact* as this?

"You inhale chlorine gas, and have induced a violent wheezing cough, with expectoration."

"Chlorine has become famous in cough affections, particularly in phthisis."

Wherein has chlorine become so notoriously famous in phthisis, as in its failures?

"Your horse is about to shy from fright."

"You strike him, and by this other fright prevent his shying."

This is not good horsemanship, much less has the inference any logical truth.

Homœopathy, as we have been often told already, teaches that the action of medicines is in conformity to the following law:—

"Diseases are cured most quickly, safely, and effectually, by medicines which are capable of producing symptoms similar to those existing in the patient, and which characterise the disorder." In this supposed law the author rejoices greatly, and on it enlarges quite in the "Ercles vein." He is especially strong on its certainty: thus—

"to cure a disease, all that is required is to find a substance, either presented in nature or contrived by art, which, if taken by a person in health, will produce in him symptoms similar to those manifested in the disease: give that to the diseased, and the disease will be cured." (p. 65.)

This is just the point of its greatest *uncertainty*, and the source of all error in this "system." Here a fundamental fact is assumed, and then reasoned upon in the style we have already quoted, instead of establishing an induction from an extended series of observed facts. It will serve but to a very small extent to hide this defect, that the homœopaths collect a long string of what they call the "uncertainties" of

the "old system." Such constitutes the greater portion of Dr. Epps's work.

The following is a specimen of the author's line of argument respecting the virtues of trituration and infinitesimal division of doses:—

"Every one is aware of the facts,—that, if eau de Cologne is rubbed on the hand, it gives out a scent much more intense than that given out without such friction; if a leaf of geranium is squeezed, it gives out a scent excessively strong."

What becomes of the principle *similia similibus*, after the following assertion, which we have marked with italics?—

"Those opponents, then, who argue that medicines in infinitesimal quantities do not act upon persons in health, waste much time, and expend uselessly much trouble. *No homœopathist maintains that they do.*"

"The opponents of homœopathy," observes Dr. Epps, somewhat triumphantly, "allow that patients, whose diseases have resisted all other treatment, whether allopathic, antipathic, or both, *do get well under homœopathic treatment.*" True; and so a large proportion of patients would under any harmless system of do-nothing treatment, *if they have only faith enough therein to let themselves be cured.* But, on the other hand, how is it that, when

homœopathic treatment has been employed in acute disease, the practitioner has been obliged to have recourse to the "old system" either himself, or to call in the aid of some other practitioner really competent to treat disease?

Dr. Epps states several of the objections that have been urged against homœopathy, and, we suppose, considers that he has refuted them. We cannot join him in his opinion.

We looked for some solid facts in this exposition of homœopathy, put forth by one of its chief advocates; but we find nothing of the kind beyond the reiterated assertion of the principle with which the author starts, which is, however, entirely taken for granted, and which he seeks to maintain by the aid of a great deal of matter extraneous to the point, interspersed with very full accounts of every weak point in the practice or in the theory of the "old system."

In answer, then, to the question, what is Homœopathy? we have, instead of a "*Demonstration*," a very pretty theory, wonderfully clear, and easy to be carried out in practice, and very sure in its results, *if only it were true*: that it is so, Dr. Epps's assertions have not shown. That the very reverse is true of this system we affirm, from having witnessed its evil results in the fact that disease has been allowed to go on to the destruction of tissues and organs, without the slightest attempt at arresting its progress. The pure homœopathist, however honest he may be in his belief, is practising only an absurdity; he does nothing, but he also ~~un~~ does nothing. The system of Hahnemann is opposed to every principle of the "old system," and proceeds on theoretical grounds the very reverse of those long established by medical science. There is, therefore, no room for a compromise between the two "systems;" and yet, opposed as these are, there are practitioners who undertake to combine the two, or administer medicines to their patients according to the rules of either. Such practitioners, it is clear, must abandon the doctrines of both, and must also possess in a very homœopathic proportion an appreciation of ethical principles. With such laxity, however, we certainly cannot charge Dr. Epps.

We shall only observe, in conclusion, that from the proved inadequacy of "globules" to relieve the symptoms of

acute disease, it is obvious that no medical practitioner can attend such a case in conjunction with a sincere homœopathist, without rendering himself an accessory before the fact to the destruction of the patient. There is no *mezzo termine*: he must either expel the homœopathist and his globules from the sick chamber, or coolly acquiesce in allowing him to die for the want of proper treatment.

On Tic Douloureux and other Painful Affections of the Nerves: with Suggestions for their Treatment by means of the Aneuralgicon; illustrated by numerous Cases, and an Engraving of the Apparatus. By C. TOOGOOD DOWNING, M.D., M.R.C.S. Pamphlet, small 8vo. pp. 73. London: Churchill. 1849.

THE author in the first place gives the varieties of neuralgia and tic douloureux, their diagnosis and treatment, and then introduces to the reader's notice the method of cure which it is his purpose, by the present publication, to make known to the profession: thus—

"From considering tic douloureux as often a local disease, depending on a state of excessive irritability, sensibility, or spasm of a particular nerve, and observing the effect of topical sedatives, I was led to the conclusion, that the most direct way of quieting this state was by the application of warmth and sedative vapour—something to soothe the nerves, and calm them into regular action. For this purpose I invented the Aneuralgicon, and it appears to answer the purpose admirably."

The author explains its nature as follows:—

"The Aneuralgicon is a name (compounded of *a-neurpa-algos*) applied to an instrument used by me for the purpose of allaying pain in nerves. It is a kind of fumigating apparatus, in which dried herbs are burnt, and the heated vapour directed to any part of the body. It is very simple in construction, and consists of three parts, with their media of connection—a *cylinder*, for igniting the vegetable matter; *bellows*, for maintaining a current of air through the burning material; and *tubes and cones*, for directing the stream of vapour." (p. 27.)

The plants which have been employed by the author are belladonna, henbane, cannabis indica, tobacco, aconite, stramonium, hemlock, digitalis, &c. These materials, being ignited, are placed in the cylinder; the fire may be urged by the

bellows to any degree of intensity, so that, besides the sedative, a rubefacient effect may also be obtained.

Dr. Downing speaks very strongly in favour of this instrument from his own experience. Cases are added in which the author had effected cures when every other means had failed. If the employment of this instrument be equally successful in the hands of others, medical practitioners will have reason to be thankful to Dr. Downing for an efficient remedy in a hitherto almost intractable complaint.

Proceedings of Societies.

ACADEMY OF MEDICINE, PARIS.

August 6, 1850.

Acute Rheumatism.

M. ANDRAL observed that, in the late discussion on the subject of acute rheumatism, one of the most important points brought under consideration was the state of the joints. M. Andral read the notes of a case in which he had recently had an opportunity of examining the morbid alterations that had been produced by this disease. The shoulders had been the seat of the affection, which was simple uncomplicated acute rheumatism. The patient, an aged woman, was debilitated by an attack of pneumonia when the rheumatism occurred: she had died in about eight days without an apparently sufficient cause. The interior of both scapulo-humeral articulations contained homogeneous pus, having all the characters of that which is the result of phlegmonous inflammation. The surfaces presented innumerable minutely injected vessels, forming the closest network, except on the articular cartilages, where this injection was but slightly marked. The bursæ about the joints were also filled with pus. The parts external to the joints, as the muscles, ligaments, &c., were in their normal condition. The cavity of the right knee-joint contained a quantity of fluid somewhat doubtful in appearance; but all other articulations were carefully examined, and nothing abnormal found.

Application of Electricity in Diagnosis.

M. MARTINER read an essay on this subject, and stated the following conclusions:—

1. The explosion of contractility and

sensibility by the aid of electricity is of value in the diagnosis of those diseases in which these are compromised. 2. The degree of contractility exhibited during the passage of electricity in paralysis of movement, furnishes a means of diagnosis, as does also the amount of electrical sensibility in paralysis of sensation. 3. The presence of electrical contractility is the distinctive character of cerebral, hysterical, and rheumatic paralysis; its absence is an indication of disease of the spinal cord.

SURGICAL SOCIETY OF PARIS.

August 7, 1850.

Imperforation of the Rectum—Operation—Cure.

M. DENONVILLIERS presented an infant upon whom he had operated successfully. The child (a male) was taken to him three hours after its birth. The genitals were divided into two distinct lobes by a vertical line: these lobes, which contained each a testicle, resembled enlarged labia. The glans, devoid of prepuce, was situated at the superior part of the fissure. The raphe was displaced toward the left side. The situation of the anus was occupied by a depression presenting cutaneous folds converging to the centre, and which, when the child cried, showed the action of a sphincter. A minute orifice, whence exuded apparently sebaceous matter, existed a little to the right of the depression. There was no protrusion, as of meconium, beneath the depressed integuments. M. Denonvilliers made an incision through the situation of the anus, and with some difficulty found the rectum, which terminated at a short distance above the seat of the depression, and was displaced towards the right. When cut into, no meconium at first escaped; but, by the use of an enema, a considerable quantity, in a hardened condition, was removed. The operation was completely successful in establishing the functions of the intestine and anus.

A long discussion followed, which was terminated by M. Denonvilliers promising to prepare a memoir on this subject.

THE CHOLERA AT MALTA.

LETTERS from Malta of the 2d inst. state that cholera was still raging there. On the 2d there were 69 cases and 41 deaths. The local government was censured for not issuing bulletins of the daily progress and fatality of the disease. The fleet was still in its cruising ground.

Hospital and Infirmary Reports.

ST. BARTHOLOMEW'S HOSPITAL.

Atonic Distention of the Bladder, Stricture, and Abscess in the Urethra.

W. W., *et.* 53, has had a stricture in the urethra for twenty-three years, during which time he has been under the care of several surgeons, and has had catheters passed repeatedly, sometimes for the sake of merely dilating the stricture, and sometimes to draw off the urine which has been retained. Retention has occurred frequently, but generally without much pain, although his bladder has sometimes been so much distended that two pints of water have been drawn off on the introduction of a catheter. It is now six months since a catheter has been introduced, and he has suffered from great straining and increased difficulty in voiding urine, which has lately only passed in drops; for the last three months he has observed a swelling in the lower part of his belly. He came to the hospital on July 31st, and was admitted under Mr. Stanley. A considerable swelling, evidently containing fluid, occupied the hypogastric region, and extended upwards to the umbilicus; it was not painful on pressure, nor had it the defined firm outline of a distended bladder, but was loose and flaccid, and very much resembled ascites: in fact the patient had been under treatment for this disease prior to his admission. He did not experience the uneasiness and desire to make water which usually accompanies retention of urine; the skin was hot, the tongue tolerably clean, and the pulse natural; the spongy part of the urethra, at one point in the perineum, was hard and slightly swelled. Mr. Stanley introduced No. 4 catheter, but not without some difficulty; and, before entering the bladder, the instrument made its way through a collection of pus situated in the neighbourhood of the bulb, and communicating with the urethra: the pus escaped through the catheter, and continued to do so until it was fairly in the bladder, when the urine flowed freely, and sixty-five ounces were drawn off. The swelling in the hypogastrium subsided, and intestines, filled with flatus, took its place.

Aug 1st.—As no urine has passed since yesterday, the catheter was introduced, and two pints were drawn off; some pus escaped from the urethra; the catheter was fastened to the penis and allowed to remain in the bladder.

3d.—The catheter slipped out of the bladder last night, but he has since voided a pint of urine by the natural efforts: it

passed in drops only. The swelling and hardness has nearly disappeared from the perineum; the skin is moist, the tongue clean, and there is no swelling in the hypogastrium.

Dislocation of the Hip in a child eighteen months old.

The infrequency of dislocation of the hip at such an early age renders this case interesting. The little child was brought to the hospital on July 29th; its friends could not give an accurate account of the manner in which the accident happened, but they believe a slight fall was the cause. The head of the femur was resting on the dorsum ilii; there was great mobility of the limb, and it was reduced with the greatest ease.

Operations performed on Saturday, Aug. 3.

Carcinoma of the Breast.

The first patient brought into the operating theatre was Mary W., *et.* 47, suffering from carcinoma of the right breast. She is the mother of two children, and first discovered the disease about two years ago, when it was in the form of a small hard knot on the side of the breast, immediately beneath the skin; but it now occupies the whole mammary gland and a portion of skin which is adherent to it. It has lately increased rather rapidly, and an operation was deemed expedient. When the patient had become insensible from inhaling chloroform, Mr. Skey commenced by including the nipple and diseased skin within his incisions, which were carried round the mammary gland, and this was dissected from the pectoral muscle: some enlarged glands were then removed from the axilla; a few vessels were secured, and the wound was closed by a broad strip of adhesive plaster. The operation lasted but a short time, and very little blood was lost.

Chimney-sweepers' Cancer.

The next was a case of chimney-sweepers' cancer on the scrotum of a strong and otherwise healthy man, *et.* 33, of temperate habits, who resides in Essex, and has been a chimney-sweeper for twenty-five years. This is the second time he has suffered from the same disease: on the first occasion, also, he was in the hospital under Mr. Stanley, and had a similar cancer removed, only one year ago, from the left side of the scrotum; he then returned to Essex, after having been in the hospital a month, and was obliged to resume his occupation before the wound was quite healed; it healed, however, in about two weeks, and he remained sound for three months, when a small lump appeared near the lower extremity of the old cicatrix; the lump in

creased, crusted over, cracked, ulcerated, and discharged a thin offensive matter; the ulceration increased and became painful, and at last compelled him to give up his work and return to the hospital, where he was again admitted, under Mr. Stanley, on July 25th, 1850. The disease occupied a considerable portion of the integument of the scrotum, as well as some of that on the root of the penis. Its appearance was that of an irregular ulcer, with hard elevated edges; it inclined rather to the right side of the scrotum, and did not follow the course of the old cicatrix, although they approached each other at their lower part; the old cicatrix was quite sound; the testicles, spermatic cords, and inguinal glands, were also sound.

Chloroform was administered to the patient, and Mr. Stanley removed the entire morbid structure by dissecting it from the subjacent tissues: at one point it was found adhering to the right tunica vaginalis; a small portion of this structure was therefore removed, and the testicle consequently exposed. A few bleeding vessels were tied, and the wound was closed with sutures.

Lithotomy.

The operation of lithotomy was then performed by Mr. Lloyd on Wm. M'Clare, *et. two years and nine months.* This little patient has had symptoms of stone for six months; and although he has suffered less pain than is usual, he has been unable to retain his urine, which has continually dribbled from him: he is of a delicate frame, and frequently suffers from an extensive prolapse of the rectum. The introduction of a sound, a few days ago, though performed when the patient was under the influence of chloroform, brought on such straining as to cause the gut to be protruded to a considerable extent—a prospect not at all encouraging to the operator.

On his being placed on the table a curved staff was introduced, and the patient was quickly under the influence of chloroform. Mr. Lloyd proceeded to perform the lateral operation in the usual way, using a straight knife convex on its cutting edge, and with a somewhat rounded extremity. As was expected, the rectum protruded, but was avoided without much apparent difficulty. Two stones, rather larger than filberts, were extracted. A gum-elastic tube was introduced through the wound, and the patient was sent to bed.

Medical Intelligence.

ADMIRALTY CIRCULAR RESPECTING THE RANK AND POSITION OF ASSISTANT-SURGEONS.

"My lords commissioners of the Admiralty are pleased to direct that the following regulations be established with reference to the rank and position of the assistant-surgeons of the Royal Navy:—

"1st. The assistant-surgeons are to be divided into two classes.

"2d. The first class is to consist of all those who have completed three years' servitude from the period of their first entry, one year of which, at least, must be on board a commissioned ship, and the other two may be served in one of H.M. Naval Hospitals, and who have passed the examination for surgeon, either at home or abroad, as directed by the Admiralty Instruction (Chap. II. Art. 26, p. 26); but in case the service on which the ship may be employed, should render it impossible that three surgeons can be assembled for a considerable period of time, then the captain may give an order to the surgeon of the ship to examine the assistant-surgeon whose period of time has expired, and, if found competent, may grant him a temporary certificate until the regular officers be assembled.

"3d. Assistant-surgeons who have served more than three years, and who have passed the examination for surgeon under the above conditions, are to rank next to naval instructors, and are to mess with the ward-room officers, to be allowed cabins when the accommodation and space on board will admit.

"4th. The second class of assistant-surgeons is to consist of all those who have not served three years, and those who have not passed their examination for surgeon.

"5th. The cabins specified in their lordships' order of the 26th of February, 1846, are to be strictly appropriated to the officers mentioned in that order, and their lordships' instructions on that head are to be fully carried out.

"6th. First-class assistant-surgeons, who may be serving in small vessels commanded by lieutenants, are to mess in the gun-room with the other officers.

"7th. The above regulations are to be carried into effect on the receipt of this circular order.

"By command of their lordships,
" (Signed) J. PARKER.

"Admiralty, July 17, 1850."

As soon as the Admiralty minute was promulgated at Portsmouth, relative to the

award of the privilege of the ward-room to assistant-surgeons, Captain Sir Henry Blackwood, of Her Majesty's ship *Vengeance*, issued an order that the assistant-surgeons of the *Vengeance* should take their seats in the ward-room.

DEATH FROM POISONOUS FUNGI.

LAST week Mr. Pratt held an inquest at Wisbeach Fen upon the bodies of Patrick Hunt, an Irishman, 18 years of age, and Winifred Garvey, 28 years old, wife of — Garvey, also an Irishman, when the following particulars were elicited:— Patrick Hunt, on the 2d inst., when walking by the Thorney Road side, saw and gathered a small quantity of what he thought were mushrooms, which he carried to his lodgings. He ate a portion himself, and gave some to Mrs. Garvey, who also ate a few, and gave a small quantity to her child, a girl 2 years old. They did not experience any serious effects that day, but at day-light on Saturday morning they were all attacked by violent sickness and purging, accompanied by great pain in the stomach and bowels. Neither the sufferers or their friends appear to have apprehended any danger; but on Saturday evening Hunt became suddenly worse, and died about 8 o'clock. At that time Mrs. Garvey's husband returned from work, and finding his wife much weaker and in pain he became alarmed, and medical attendance was obtained. On Sunday morning, however, she died; the child lingered until Monday morning, when she died also. The fourth death was that of Thomas Howd, an Irish child in another family, who it seems also partook of mushrooms, but not a portion of those eaten by the three first attacked, nor, as far as is at present known, gathered at the same time. A *post-mortem* examination of the body of Mrs. Garvey was made, when extensive patches of inflammation were found in the stomach and small intestines, very similar to those which are seen in cases of poisoning by arsenic.

PRESENTATION OF THE SWINEY PRIZE GOBLETS TO DR. PARIS AND M. FONBLANQUE.

AT the late annual distribution of the Rewards of the Society of Arts, Lord Colborne in the chair,—two silver cups, executed by Messrs. Garrard, after the design of Mr. MacIise, were presented to Dr. Paris, President of the Royal College of Physicians, and Mr. J. S. M. Fonblanque—the two cups being in place of a single one, which, in accordance with the will of the late Dr. Swiney, was last year given to 1000 gentlemen as joint authors of the *last treatise on Medical Jurisprudence.—The Lancet.*

THE POSITION OF MEDICAL PRACTITIONERS IN TURKEY.

THE government of the Sublime Porte has ordered the creation of a class of salaried public medical officers, whose duty is to attend gratuitously both rich and poor. From the latter they are expressly forbidden to receive any gratuity; from the rich, however, they are at liberty to act as their judgment dictates. They hold their appointment on condition of forwarding to the government a quarterly report of the number of cases attended, the nature of their diseases, the number of deaths, &c., with a meteorological record of the same period, and hygienic observations in reference to epidemics, intramural interments, &c. X

RE-VACCINATION IN PRUSSIA.

RE-VACCINATION is systematically practised in Prussia. No child is admitted into a school without proof of vaccination, and every recruit is vaccinated on admission into the army. In the year 1848, twenty-eight thousand eight hundred and fifty-nine soldiers were vaccinated: of these, the vaccine disease was regular in sixteen thousand eight hundred and eighty-two; in four thousand four hundred and four individuals it was irregularly developed; and in seven thousand five hundred and seventy-three it did not take any effect.

EPIDEMIOLOGICAL SOCIETY.

THE first meeting of the Council of the Society for the Investigation of Epidemic Diseases was held at the residence of Dr. Babington, the President, on the 9th inst., when Dr. Addison was nominated as Treasurer, Dr. Roupell and Mr. Nussey as Auditors. Sub-committees were appointed to frame a code of laws, and for other purposes. Interesting communications were read from abroad by the President. The meeting was well attended, and the Secretary reported that several new members had joined the Society.

UNIVERSITY OF ST. ANDREWS.

LIST of gentlemen who had the degree of M.D. conferred upon them, 3d of August, 1850:—William David Adams, M.R.C.S. Ed.; John M. Ballenden, L.A.C. Eng., and M.F.P.S. Glasgow; George Phillips Bevan; Walter Thompson Boddy, M.R.C.S. Eng.; John Young Bown, M.R.C.S. Ed.; John Campbell, M.R.C.S. Eng. L.A.C.; Richard Chapman, M.R.C.S. Eng.; Thomas Clarke, M.R.C.S. Eng. L.A.C.; William Simpson Craig, M.R.C.S. Ed.; John Thomas Dolman, M.R.C.S. Eng. L.A.C.; William Dean Fairless, M.R.C.S. Eng.; Richard Ford Foote, M.R.C.S. Eng.; Joseph Wilcox Haddock, L.A.C.; Joseph

Hewitt, M.R.C.S. Eng. L.A.C.; Thomas Coke Higga, L.A.C.; James Harvey Lilley, M.R.C.S. Eng. L.A.C.; Andrew Loewner; John Lyall, M.R.C.S. Ed.; Henry Madge, M.R.C.S. Eng. L.A.C.; Robert Slater Mair, M.R.C.S. Ed.; Charles Robbins Maxwell, M.R.C.S. Eng.; Alfred Peckett, M.R.C.S. Eng. L.A.C.; Benjamin Francis Popham, M.R.C.S. Ireland; Robert Rooke France, M.R.C.S. Ed.; William Richardson, A.M. M.R.C.S. Eng.; Robert Ripley, M.R.C.S. Ed.; Edward Seemka, M.R.C.S. Eng.; John Thomas Small, M.R.C.S. Ed.; Alexander Macfie Smith, M.R.C.S. Ed.; Hugh Thomson, M.R.C.S. Ed.; George Brown Turner, M.R.C.S. Eng. L.A.C.; Henry Noble Watson, L.A.C.; James Whitehead, F.R.C.S. Eng.

FELLOWSHIP OF THE ROYAL COLLEGE OF SURGEONS.

At the last meeting of the council of the institution, Mr. Cornelius James Philbrick, of Kidderminster, was admitted a fellow of the College, having previously undergone the necessary examination for this distinction: this gentleman's diploma as a member is dated August 17, 1888.

ROYAL COLLEGE OF SURGEONS.

GENTLEMEN admitted members on the 9th inst.:—Messrs. T. A. Brandt.—R. T. Cashe.—B. Carrington.—T. Mawhinny.—J. C. Bury.—J. H. Smithwick.—M. M. McKensie.—A. Hill.—T. Scattergood.—T. Riordan.—T. Creed.

Admitted on the 12th inst.:—Messrs. G. H. Watts.—H. Behrend.—M. Egan.—W. H. Clarke.—G. Ridsdall.—W. T. King.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 8th August, 1880:—Thomas Scattergood, Leeds, Yorkshire—Sidney Henson, Hull, Yorkshire—Harvey William Dixon, Putney, Surrey—William Peck, Sharnbrook, Bedfordshire—Samuel Hayman Warren, Milverton, Somerset—Edward Ralph Allen, York—James Edward Dickinson, Hart Street, Bloomsbury Square—Herbert John Walker, Sheffield, Yorkshire—Henry George Allanson, Scarborough—James Croston, Atherton, Manchester—Nathaniel Watton Jones, Chichester—Charles Whetmough, Woore, Salop—William Blackborne, Clapham, Great Baddon, Essex—Christopher Nugent Spinks, Ireland—William Robey Strelley, Oakenhorpe, Derby.

METEOROLOGICAL.—The mean temperature of the week was 5° above the mean of the month.

NOTICES TO CORRESPONDENTS

Communications have been received from H. Lonsdale and Dr. Fearnside.

Dr. Fearnside's paper will be inserted, and proof sent.

The letter of Mr. Rose, and the papers of E. Snow and Mr. Bate, will appear in the following number.

CORRECTION.—In Dr. THT's paper, in last number, page 235, col. 1, 13 times *sum* for "hermetic," read "hemetic."

Lectures.

COURSE OF LECTURES

ON

DISEASES OF THE HEART.

Delivered at St. Vincent's Hospital during the Session 1849-50.

BY O'BRYEN BELLINGHAM, M.D.

Fellow of, and Member of the Court of Examiners of, the Royal College of Surgeons in Ireland, and one of the Medical Officers of the Hospital.

LECTURE X.

EXAMINATION OF THE HEART IN DISEASE, CONTINUED.

Abnormal sounds developed during the heart's action—Pericarditic friction-sounds—Endocardial or valvular murmurs—Bruit de soufflet—Circumstances under which bruit de soufflet is heard—Conditions under which bruit de soufflet is developed—Mechanism of production of bruit de soufflet—Bruit de soufflet at the right side of the heart—Conclusions from the presence of bruit de soufflet.

Abnormal sounds developed during the heart's action.

THE sounds which either replace or accompany the normal sounds of the heart, and which are new, morbid, or abnormal sounds, were first named *murmurs* by Dr. Forbes; and this term has been very generally retained since. They present different characters in different cases of disease, being sometimes blowing, sometimes resembling rather the sounds of sawing, filing, grating, whistling, &c.: and this circumstance has been deemed by some writers of sufficient importance to form the ground of their classification, and they have been divided into the "sounds of blowing," and "sounds of friction;" but as in every instance they are the result of *friction*, generally between a liquid and a solid, sometimes between two solids, they would be more correctly classified according to their seat. Thus, sometimes they have their seat exterior to the heart, and between the opposed serous surfaces of the pericardium: these are the *pericarditic friction-sounds*, or the *peripheral or exocardial murmurs*. Sometimes they have their seat within the heart, and at the orifices of the ventricles: these are the *endocarditic, endocardial, or valvular murmurs*. Sometimes, again, they have their seat in the large arteries; at others, in certain veins: the former are the *arterial*, the latter the *venous murmurs*.

The abnormal sounds developed during

the heart's action will be considered here in the following order:—

1st. The *pericarditic or exocardial murmurs*, or the *peripheral friction-sounds*; which accompany the movements of the heart, but do not interfere with its intrinsic sounds.

2d. The *endocardial or valvular murmurs*, subdivided into the *systolic and diastolic*, which either take the place of the normal sounds of the heart, or prevent them from being heard.

3d. The *arterial murmurs*.

4th. The *venous murmurs*.

It will now be necessary to describe these sounds. To be appreciated, however, they must be heard: no verbal description can supply its place.

Pericarditic friction-sounds.—The abnormal sounds which have their seat between the opposed serous surfaces of the pericardium are termed *attrition murmurs*, or *friction-sounds*, from their character; and *pericarditic, exocardial, or peripheral murmurs*, from their seat. Although all the abnormal sounds which we have now to consider are the result of friction, the *exocardial murmurs* are more particularly entitled to the name, because the friction here takes place between two solids: in all the others, one of the agents in the production of the sound is a liquid.

In a state of health, the opposed serous surfaces of the pericardium being exceedingly smooth, and constantly moist, glide over one another, during the motions of the heart, without producing any sound, or, at least, any which can be detected by the ear applied to the parietes of the chest. When, however, as the result of inflammation, lymph is effused upon this membrane, and its opposed surfaces become rough, unequal, or irregular, friction to a greater or less degree takes place during the movements of the heart; and this friction develops sound, which becomes audible when the stethoscope is laid upon the parietes, and is frequently sufficiently strong to communicate a distinct vibratory sensation to the hand, as was first pointed out by Dr. Stokes; and according as the action of the heart is violent or feeble, and as "the lymph effused is small in quantity, partially deposited, and forms a thin, smooth layer, or is copious, hard, and irregular, the sounds will vary from the slightest degree of rubbing, to a loud, harsh, grating, or creaking sound."

The attention of the profession was first called to the friction-sounds of pericarditis by Dr. Stokes.* M. Collin,† it is true, had described the *bruit de cuir neuf*, one

* Dublin Journal of Med. Sciences, Sept. 1833.

† Les Diverses Méthodes d'Exploitation de la Poitrine. Paris, 1834.

of the rarest of these sounds, and Broussais* had noticed a friction-sound in pericarditis similar to that of two dry bodies, like parchment, rubbing against one another; but their remarks attracted no attention: it was reserved for Dr. Stokes to point out the distinction between the physical signs of the two forms of pericarditis; to determine those which belong to the variety of the disease in which the opposed surfaces of the pericardium are coated with lymph; and to demonstrate that this form of pericarditis, which heretofore had been supposed to yield no stethoscopic signs, was really the one in which auscultation is of the greatest assistance to the diagnosis. Dr. Stokes's paper, entitled "Researches on the Diagnosis of Pericarditis," was published in September 1838; in the following year M. Bouillaud† description of the friction-sounds of pericarditis appeared; and, in the year 1835, Dr. Watson,‡ in giving the details of two cases of pericarditis, described the friction-murmur heard in them under the name of the "to-and-fro sound."

The friction-sounds of pericarditis have received various names. They may all, however, be included under the following heads, originally laid down by Dr. Stokes in the paper to which I have referred:—

1st. "A slight friction-sound, perceptible only at the very commencement and at the termination of each diastole and systole of the heart."

2d. "A rasping-sound, very similar indeed to that produced in the worst cases of ossification of the valves. In others the sound is similar to the frotement of pleurisy, only modified by the action of the heart."

3d. "The sound resembles the creaking of new leather, to which it was originally compared by Collin."

The slight friction-sound, the "bruit de frottement" of the French, resembles the sound produced by rubbing the hands together, or the rustling noise produced by crumpling the paper of which bank-notes are made, to which M. Bouillaud compared it, or the rustling of silk; or, when stronger, the crackling of parchment. According to Dr. Hope, this sound is produced by the presence of soft wet lymph upon the opposed surfaces of the pericardium. It seems to me to be a probable supposition, that in the cases of pericarditis in which this sound is alone heard, and where all through it preserves the same character, it is due to the lymph being deposited

merely upon one of the opposed surfaces of the pericardium.

The rasping sound.—The *bruit de rapement* or *bruit de frottement* of the French, has, as its name denotes, a harsh rasping or grating character; it often resembles accurately the rasping or the sawing of wood. The sound which it appeared to me most closely to resemble on several occasions was that which would be produced by scratching with the nail the surface of dry bone. It constitutes the to-and-fro rubbing sound of Dr. Watson. Dr. Hope refers this sound to the presence of firm and rugged lymph, the sound being loud in proportion as the lymph is rough, and the action of the heart strong.

The creaking sound of new leather, the *bruit de cuir neuf*, is one of the rarest of these sounds; it resembles accurately the creaking of a new saddle, but is not so loud; it may be imitated, Dr. Hope observes, "by rubbing together the fingers made sticky by resin." We had lately a case in hospital where a sound very similar to this was developed in the bronchial tubes, owing to their obstruction by tough mucus: here, however, it of course accompanied only the respiratory movements. This creaking sound was supposed by Dr. Hope to depend upon the adhesive nature of the lymph, and to be an indication that adhesions were about to take place. More recent observations have, however, shown that this is not necessarily the case. Dr. Copland* refers it to thickening or condensation of the sub-serous and serous tissues of the pericardium, especially of that portion reflected over the heart; and the formation of a dense and elastic false membrane.

Another sound has been described by Dr. Hope under the name of the "continuous rumbling murmur," which he refers to the presence of a small quantity of fluid in the sac of the pericardium, the opposed surfaces of which are also coated with lymph. He supposed that the agitation or "churning of the fluid during the motions of the heart produces the sound." It is more rare than any of the other pericarditic murmurs, with the exception, perhaps, of the *bruit de cuir neuf*.

Conclusions respecting the pericarditic friction-sounds.

When I come to speak of pericarditis, I shall have occasion again to recur to these sounds. It will be sufficient here to observe—

1. That they are almost limited to cases of inflammation of the pericardium; that

* Commentaires des Propositions de Pathologie, tome i. 1829.

† Dict. de Méd. et de Chir. Prat., art. Pericardite. 1834.

‡ LONDON MEDICAL GAZETTE, April 1835.

* Dict. of Pract. Medicine, vol. ii.

they are pathognomic of one form of this disease, and constitute the most valuable diagnostic signs of it.

2. That they have all, more or less, a friction or attrition character.

3. That they are almost always double, and are usually better marked during the period of the ventricular systole than during the diastole.

4. That they appear to be superficial and near, and are seldom audible much beyond the limits of the præcordial region.

5. That they do not, like the murmurs next to be described, replace the ordinary sounds of the heart, but are heard independent of them.

6. That their duration is usually short; frequently ceasing entirely after having been heard for a few days, and not unfrequently changing their character within the period that they are audible.

7. That they are frequently accompanied by a peculiar vibration or *frémissement* sensible to the hand laid upon the parietes.

8. That a bruit de soufflet at one of the orifices of the left side of the heart, the result of endocarditis, not unfrequently coincides with these sounds.

Endocardial or valvular murmurs.—The abnormal sounds which have their seat at the orifices of the ventricles, and which replace or accompany the normal sounds of the heart, constitute the most valuable signs of disease of the valves or orifices of the left side of the organ. They present several varieties in different cases,—being sometimes blowing, when they constitute the varieties of the bruit de soufflet or bellows-murmur; sometimes rough and harsh, resembling the familiar sounds of sawing, rasping, or filing; and at other times having a whistling or musical character, constituting the varieties of the bruit de soufflet musicale, or musical murmur.

Bruit de soufflet.—The bruit de soufflet or bellows-murmur, as the name denotes, has a blowing character, and is by many degrees the most frequent abnormal sound heard in diseased states of the valves or orifices of the heart. It was discovered and named so, by Laennec, from its similarity to this well-known sound, to which it often bears a most ridiculous resemblance. Bruit de soufflet does not always however, present the same character: sometimes it is perfectly smooth and soft; at other times it is loud and rough; sometimes it is a mere whiff: at others it is prolonged and lengthened out. It may accompany or replace either the first or the second sound of the heart, more frequently the first; or it may pass into a sawing, rasping, or musical murmur. In the vast majority of cases of disease, it is limited to the left side of the heart.

Circumstances under which bruit de soufflet is heard.

Bruit de soufflet is heard in various and different lesions of the valves and orifices of the heart; it is not, however, limited to diseased states of this organ, but becomes audible under a variety of other circumstances, as we shall presently see. Thus, it is heard when there is any obstacle to the free passage of the blood through the orifices of the left side of the heart, or when the valves imperfectly perform their functions, and permit regurgitation. It is heard in aneurism of the left ventricle and in congenital malformations of the heart, where a communication exists between the ventricles. It is heard in cases where the lining membrane of the arch of the aorta is diseased, and in aneurism of all the large arteries. It is heard in aneurismal varix, where a communication exists between an artery and a vein, in varicose aneurism where a small sac exists between them, and in the pulsating form of aneurism by anastomosis. It is frequently heard in cases where no disease of any kind exists in the heart or arterial system, but where the quality of the blood is altered; where this fluid has become more watery and less viscid than natural. Finally, it can be developed at any time in the heart and arteries by suddenly abstracting a large quantity of blood, as was first pointed out by Dr. Marshall Hall; or in a large artery by making pressure upon it so as to diminish its calibre.

Bruit de soufflet may be developed in the cavity of the chest by the growth of a tumor of any kind, which comes to press upon the aorta or its branches, or upon the pulmonary artery; or by malformation or deformity of the chest, owing to disease of its bony parietes, by which the heart's movements are impeded or the large vessels are compressed. Bruit de soufflet is said to have sometimes been heard for the first time, a short period previous to death, in the advanced stage of pulmonary or other diseases: M. Bouillaud refers it then to the formation of fibrinous concretions in the cavities of the heart, which interfere with the action of the valves, or obstruct the orifices. It is temporarily heard in violent palpitation in hysterical subjects, or in attacks of palpitation in cases where the left ventricle is hypertrophied, and its cavity dilated: here it disappears as the palpitation subsides. Bruit de soufflet, in a very marked form, is likewise heard from the fourth month to the end of pregnancy: here its site is usually the iliac fossa, sometimes on both sides, more frequently only on one side.

Dr. Graves* has noticed the remarkable

fact, that a bruit de soufflet is sometimes audible, in the second stage of pneumonia, over the affected lung, which disappears as the symptoms of the inflammation subside: it is not perceptible in the subclavian or carotid arteries of the same side, and probably, when present, depends upon pressure on the branches of the pulmonary artery. Dr. Latham* has called attention to the circumstance that a gentle bruit de soufflet, which coincides with the ventricular systole, is heard occasionally in phthisis: it is not perceived in the præcordial region, but in a circumscribed space above it and on the left side. M. Zehetmayer† has confirmed the correctness of Dr. Latham's observation, and would appear to have noticed this murmur previous to the publication of Dr. Latham's work. He says, "I have repeatedly heard, in phthisical persons, in the second intercostal space, a decided bellows-murmur, instead of the first sound of the pulmonary artery; and in a place where there was no doubt that tubercular infiltration was present. No alteration in the vessel could be detected on post-mortem examination." Dr. Latham supposes that this murmur may have its cause in the pressure exercised by the diseased lung upon the pulmonary artery, and its first branches. In both the latter cases, the condensed lung, having become a better conductor of sound, conveys a murmur to the ear which would probably be inaudible if the lungs were healthy. M. Gendrin‡ has called attention to the circumstance that, in the cold stage of intermittent fever, a bruit de soufflet, analogous to that heard in cases of chlorosis, is audible on auscultation of the heart. As individuals who have been the subject of ague for any length of time are, however, in general more or less anæmic, the murmur is probably due to this cause.

Conditions under which bruit de soufflet is developed.—Whenever bruit de soufflet is heard in the heart, it arises either from contraction or some other diseased state of the orifices or valves of the heart, which impedes the free passage of the blood; or from a condition of the valves which prevents them from closing the orifice, and permits regurgitation; or from the blood being impelled with increased force and velocity through the aortic orifice, or through an abnormal orifice, as in aneurism of the left ventricle, and congenital malformations of the heart; or from some alteration in the quality of the blood itself, or in its quantity; or from the formation of fibrinous or other concretions in the cavities of the heart, which interrupt the play

of the valves, or impede the orifices; or where morbid growths are developed in the cavity of the chest, which compress or displace the heart; or where the bony walls of the thorax are deformed, and the cavity is much narrowed.

Whenever bruit de soufflet is audible in the arteries, it arises either from roughness of the lining membrane of the vessel; or from the calibre of the artery being diminished, owing to pressure upon the part; or from an altered condition of the blood; or from an aneurismal sac springing from a large artery; or where an abnormal communication exists between a large artery and a vein; or where an aneurismal sac is seated between an artery and a vein, through which the blood passes from the one to the other.

Bruit de soufflet is therefore a symptom in endocarditis, where the aortic or mitral valves are swollen, thickened, or indurated; or where vegetations form upon them, or upon the orifices; as well as in the chronic forms of disease of the valves or orifices, accompanied by contraction of the orifices, by ossific or other deposit upon the valves, or adhesion of the valves to one another or to the parietes. It will likewise be heard in cases where rupture of a valve or of a tendinous cord takes place, as well as in cases of congenital malformation of the valves, one of the most frequent of which is a cribriform condition of their curtains. Bruit de soufflet is likewise a symptom in dilatation of the orifices of the left side of the heart, without any disease of the valves, or where they are prevented by any other cause from perfectly fulfilling their functions. It is a symptom in aneurism of the left ventricle; in congenital malformations of the heart; in cases of morbid growths in the cavity of the thorax; in aneurism of all the large arteries; in aneurismal varix, and varicose aneurism; in disease of the lining membrane of the arch of the aorta; and, finally, in an anæmic state of the system whatever be its cause.

Mechanism of production of bruit de soufflet.—Laennec attributed bruit de soufflet to spasm, or to a vibratory action of the heart; Bertin, to the increased friction produced by the passage of the blood through a contracted orifice. Other physiologists have endeavoured to explain it by referring it to increased velocity of the circulation, or to very energetic action of the heart, or to "a certain resistance given to the blood moving with a certain force." Others have referred it to modifications or alterations in the tissue or structure of the parietes of the heart, or to morbid conditions of the blood itself. M. Bouilland§ is

* Lectures on Diseases of the Heart, vol. I.

† Die Herzkrankheiten, 1844.

‡ Leçons sur les Maladies du Cœur, tome I.

* Archives Gén. de Médecine, tome XI.

of opinion that bruit de soufflet may be produced under three conditions—viz. increased action of the heart; narrowing of any portion of the canal through which the blood passes; or roughness of the surface over which the blood flows. Dr. Corrigan,* who has written at length upon this subject, and who made several experiments with the object of determining the question, arrived at the following conclusions respecting the conditions necessary for the production of this sound.

“1st. A current-like motion of the blood (instead of its natural equable movement) tending to produce corresponding vibrations in the sides of the cavities or arteries through which it is moving;” and

“2nd. A diminished tension of the parietes of the arteries or cavities themselves, in consequence of which their parietes are easily thrown into vibrations by the irregular current of the contained fluid; which vibrations cause, on the sense of touch, *frémissement*,—and, on the sense of hearing, *bruit de soufflet*.”

In every instance in which bruit de soufflet is audible, it is clear that some physical agent, capable of producing it, must be in operation: now the only physical agent that is invariably in operation, and under every variety of circumstances where bruit de soufflet is heard, is increased friction between the blood and the parts along or through which it passes; which appears to be amply sufficient, not only to develop murmurs, but to convert the normal sounds of the heart into them. Thus:

1. When the orifice of the aorta is contracted, or its valves are diseased, so as to impede the direct passage of the blood, there must necessarily be increase of friction; and the normal first sound of the heart will be converted into a murmur.

2. When the mitral valve is diseased, and permits a reflux current of blood into the left auricle at each ventricular systole, a murmur will be developed, which, from its louder tone, will obscure or render inaudible the first sound of the heart.

3. When the simular valves of the aorta imperfectly close the orifice, the blood must regurgitate from the aorta into the left ventricle at each ventricular diastole; and that this occurs with sufficient force to generate a murmur, which obscures or renders inaudible the normal second sound of the heart, is well known.

4. When the left auriculo-ventricular orifice becomes dilated, and the valve cannot, from this cause, fulfil its function perfectly, regurgitation of the blood occurs at each ventricular systole, and a bruit de

soufflet is developed, which is usually sufficiently strong to obscure the normal first sound of the heart.

5. When the blood is propelled with greatly augmented force, and with increased velocity, through the aortic orifice, the amount of friction between the blood and the parietes of this orifice must be much increased; and if it is sufficiently strong to generate a murmur, this will have the characters of *bruit de soufflet*, and will take the place of the normal first sound of the heart.

6. When the lining membrane of the ascending portion of the arch of the aorta loses its natural smoothness and polish, the friction between the blood and the part along which it passes must be increased; and, if the heart's action is strong, a murmur will be developed, which will be synchronous with the first sound of the heart, and will often be audible in the large vessels which come off from the arch of the aorta.

7. When the viscosity of the blood is diminished, and its watery parts are increased, a greater amount of friction will take place between this fluid and the orifice of the aorta, in its passage out of the ventricle, as well as in the large arteries, which is usually quite sufficient to convert the normal first sound of the heart into a murmur.

8. When the blood is propelled into an abnormal cavity, or through a preternatural orifice, and the action of the left ventricle is strong, the friction will be sufficient to generate a murmur which will obscure the first sound of the heart.

9. When the large arteries in the cavity of the thorax are compressed by the growth of a tumor within, or by deformity of the bony cavities from disease without, the diminution of their calibre is often sufficient to generate a murmur, which will have the character of *bruit de soufflet*, and will be heard at the period of the ventricular systole.

10. When lymph is deposited about the valves or orifices of the heart in sufficient quantity to prevent the action of the valves, or to obstruct the passage of the blood, there will necessarily be increased friction, usually sufficient to develop a murmur which may replace either the first or the second sound of the heart, or both.

11. When the fibrine separates, in the cavities of the heart, from the other constituents of the blood, and obstructs the orifices or impedes the action of the valves, if the action of the heart was strong sufficient friction would be produced to develop a murmur; but as this scarcely ever occurs, except during the last few

* *Dub. Jour. of Med. Science*, vols. x. and xiv.

hours or days of life, the current of blood is generally too feeble to develop a murmur.

12. The bruit de soufflet heard after the fourth month of pregnancy, which is not audible until the uterus has risen out of the pelvis, and which is generally known under the name of the "placental soufflet," appears to have its cause in the pressure exercised by the enlarged uterus upon the iliac arteries. Because it always accompanies the ventricular systole, it is audible usually only in one iliac fossa: and an exactly similar murmur has been heard by Dr. Montgomery* in cases where the uterus itself was enlarged from disease, or where an abdominal tumor compressed the aorta. In addition, M. Bouillaud has found that, by changing the position of the patient, the site of the murmur is altered; and Dr. Cowan† observes that the bruit de soufflet in these cases "can be detected in the femoral arteries immediately below the arch," and that "the sound may, by change of position, be transferred from one femoral artery to the other, always corresponding with the side of the uterine murmur."

In the majority of the foregoing examples the bruit de soufflet is heard at the period of the ventricular systole, and replaces or accompanies the first sound of the heart: the force with which the blood is propelled by the left ventricle being much greater than that with which it enters it, the friction between the blood and the parts along or through which it passes must be much more considerable in the former than the latter. In the former it is generally sufficient to generate a murmur, in the latter it only occasionally does so; and, when a murmur is developed, it has a different character. For instance, when the mitral valve or orifice is diseased, so as to permit regurgitation, a bruit de soufflet will be heard at the period of the ventricular systole, which quite obscures the normal first sound of the heart; when the aortic valves permit regurgitation, a bruit de soufflet is audible at the period of the ventricular diastole, which likewise obscures the normal second sound of the heart. But the two murmurs are very different: that which accompanies mitral regurgitation is loud, strong, and blowing; that which accompanies aortic regurgitation is soft, feeble, and whispering, because the force with which the blood is propelled out of the left ventricle is so much greater than that with which it enters the same ventricle.

Two or more of the conditions described above are not unfrequently combined in

the same subject; and we may have a murmur taking the place of, or obscuring both sounds of the heart; or the bruit de soufflet may pass into a sawing, rasping, or musical murmur; or, finally, the valvular disease may be complicated with an anæmic state of the system, by which the difficulty of the diagnosis is sometimes considerably increased.

Bruit de soufflet at the right side of the heart.—The foregoing remarks have reference, more particularly, to bruit de soufflet developed at the left side of the heart: in fact, this abnormal sound is very rare at the right side of the organ, because the force with which the blood enters or is expelled from the right ventricle is generally too feeble to generate a murmur; while valvular disease at this side of the heart is uncommon. Dr. Clendinning* has shown, from statistics in 100 cases, that valvular disease is sixteen times more frequent at the left than at the right side of the heart. When we consider, too, that in cases of anæmia the murmur is limited to the left side, and that murmurs from regurgitation are never, or scarcely ever, produced at the right side of the heart, we can understand why bruit de soufflet should be so rare at this side. For instance, mitral regurgitation is one of the most frequent causes of bruit de soufflet at the left side of the heart: on the other hand, tricuspid regurgitation is even more frequent; but it is not accompanied by any morbid sound, and is usually recognised by another sign,—viz. jugular pulsation. Again, aortic regurgitation is a frequent cause of a murmur at the left side of the heart, but a very uncommon cause of a murmur at the pulmonary orifice. "I believe (Dr. Hope† observes) diastolic murmur of the pulmonic valves to be exceedingly rare from disease of the valves themselves, as I have never met with a case, or been able to find one recorded." "From a rude numerical calculation (he adds) deduced from the cases that I have seen, I should think that there would be at least thirty chances to one against a murmur connected with the semilunar valves being seated in the pulmonic set."

Although the second sound at the right side of the heart is scarcely ever converted into a murmur, owing to regurgitation through the sigmoid valves of the pulmonary artery, this sound is sometimes altered, augmented, or rendered sharper, owing to hypertrophy with dilatation of the right ventricle, consequent upon disease of the mitral valve, as was first pointed out by

Skoda and Zehetmayer.* According to Skoda, when the left auriculo-ventricular valve permits regurgitation, the second sound at the pulmonary orifice becomes more intense, or sharper; which he explains by the impeded circulation through the lungs reacting upon the right side of the heart, in consequence of which the blood in the distended pulmonary artery reacts with unusual force upon the sigmoid valves of this vessel. He is even of opinion that, from this augmentation of the second sound at the pulmonary orifice, we might diagnose disease of the mitral valve or orifice previous to any abnormal sound being heard at it. Zehetmayer considers that this phenomenon is never absent in cases of mitral regurgitation, and that the diagnosis of the latter cannot be positively made unless it is likewise perceived.

A murmur at the pulmonary orifice, or in the pulmonary artery, accompanying the ventricular systole and the first sound, is less rare than any murmur at the right side of the heart. It seldom, however, depends upon disease of the sigmoid valves; in general it arises from the presence of a tumor, or from a diseased lung compressing the pulmonary artery. Dr. Hope relates a case in which an aneurism at the origin of the aorta compressed the pulmonary orifice, and contributed to produce a systolic murmur; and another, where extensive ossification of the pulmonary artery gave rise likewise to one. Dr. Elliotson met with two cases where portions of cartilage in the pericardium pressed upon and contracted the pulmonary artery so as to produce a murmur. The other circumstances under which a bruit de soufflet is developed in the pulmonary artery or its branches, owing to disease of the lungs, have been already mentioned.

Conclusions from the presence of bruit de soufflet.

The value of bruit de soufflet as a sign of disease of the valves or orifices of the heart, depends—

- 1st. Upon the period of the heart's action at which it occurs.
- 2d. Upon the situation at which it is best marked.
- 3d. Upon its character or tone.
- 4th. Upon its being constantly present or not.

In organic disease of the valves and orifices of the heart, bruit de soufflet is in a great measure limited to the left side of the organ, and has its seat either at the aortic or mitral orifice. When it replaces the first sound of the heart, it depends, in almost all cases, either upon obstructive

disease of the aortic orifice, or regurgitant disease of the mitral orifice. When it occurs at the period of the ventricular diastole, and of the second sound of the heart, it almost always has its cause in a state of the aortic valves permitting regurgitation. When bruit de soufflet accompanies both the systole and the diastole of the ventricles, it may have its cause either in obstructive disease of the aortic orifice, combined with a state of its valves permitting regurgitation; or in the mitral and aortic valves, both permitting regurgitation.

The first sound of the heart is not unfrequently replaced by bruit de soufflet when no disease of the valves or orifices exists; but a murmur is never heard at the period of the second sound of the heart, unless in cases of disease. A murmur at the right side of the heart is, as has already been observed, extremely rare; and, when it is heard, it will be found to depend more frequently upon disease of other parts than of the valves or orifices of the right ventricle.

The situation in which murmurs developed at each orifice of the heart are best heard, together with the other characters belonging to them, will be most conveniently considered when I come to describe the symptoms belonging to diseased states of the individual valves.

CASE OF CHRONIC GLANDERS IN MAN.

A MAN, aged twenty-three years, had the charge of three glandered horses for six months. Two or three months subsequently he began to suffer from stuffing of the nostrils, and discharge of thick yellow matter, with tightness of breathing. About ten months later, a small tumor appeared on the arm over the insertion of the deltoid; it continued to increase in size for three months, burst spontaneously, and was healed in about three months afterwards. At this time the discharge from the nose, which had diminished, again increased, and a tumor, of the size of a small pigeon's egg, formed over the orifice of the left lachrymal sac, burst, and left a fistulous orifice. The same then occurred on the right side.

The disease was considered to be of a strumous nature, and iodide of potassium was given; but its progress was uninfluenced. Portions of the nasal bones were exfoliated, and the patient became emaciated. In 1849, he was admitted into the hospital of Louvain. The disease continued its course, and the patient shortly sank from fever, diarrhoea, &c. &c.—*La Presse Médicale.*

ON THE CONTAINING-TEXTURE
OF THE BLOOD.

BY WILLIAM ADDISON, M.D. F.R.S. F.L.S.

[Continued from page 196.]

THE principal events demanding consideration in repair and inflammation are,—1. The accumulation of lymph or cell-particles, and, 2. The manner in which the coats of the existing blood-vessels are altered, so that blood, flowing in a multitude of new vessels, establishes cell-growth without effusion or loss of its red particles. The latter phenomenon might occur in two supposable ways—either by extension of the coats of the vessels through the newly appearing lymph-bed, or by openings effected in them becoming continuous with the new vessels. What are the facts bearing upon these alternatives?

We have seen school-boys wind a piece of twine tightly around the finger, forcing the blood with great pressure into its extremity,—they have allowed the string to remain on for some time, and, upon its removal, there did not follow any effusion or subcutaneous hæmorrhage. A very vascular nævus may be firmly pressed so as to drive almost all the blood out of its vessels, upon the return of which none of them are found to have been ruptured. The new bloodvessels traversing a lymph or granulation structure, would not for an instant bear the 1000th part of any such treatment without rupture and obliteration. Moreover, we can seldom succeed in injecting the new vessels of very recent lymph, on account of their softness or incoherency. These facts seem incompatible with the supposition that the new vessels which appear in repair or inflammation are formed by an extension of the coats of the pre-existing ones, and, in the course of our researches, we have seen nothing to lead to such a conclusion; on the contrary, the coats of newly formed vessels have always appeared altogether different from those of the older ones. The former are pulpy, soft, inelastic, and composed of colourless cells; the latter tough, elastic, and fibrous. And not

only is this the case, but it has moreover appeared, so far from the new vessels partaking of the nature of the old, *that the old become assimilated to the conditions of the new.* But let us examine, first, respecting the accumulation of the lymph particles.

The prevailing doctrine with respect to effusion of lymph and accumulation of lymph particles appears to be this:—that effusion of lymph takes place by a species of transudation or exosmosis through the coats of the vessels, and that lymph particles arise from “germs” in the fluid, which grow first as “nuclei,” and then as “cells,” these being developed “as in a blastema.” This account explains nothing as regards the principal and second-mentioned topic of the investigation, inasmuch as nothing is affirmed respecting any change in the coats of the vessels,—a change that must of necessity take place for blood to flow into new channels. There can be no doubt whatever that the fluid element of blood under various circumstances transudes the coats of the vessels,—*simple effusion*,—the coats of the vessels remaining, their elements continuing, their form unchanged. Nor do we assume to deny the *possibility* of cell particles being developed in the effused fluid “as in a blastema.” But we contend that the fact has never been proved, resting only on assumption. On the other hand, the evidence of the senses is not to be repudiated, to the effect that, after irritation, lymph, and lymph particles from the blood, accumulate on the *inside* of the irritated vessels. Having examined the changes produced in the vessels of the *conjunctiva* in purulent ophthalmia, we have found their coats altered, swollen, thickened, and made pulpy,—brought nearly to the condition of embryoniform vessels by the interposition of cell particles among the natural fibrous elements, and these have extended from the innermost boundary of the vessels where they touched the stream of blood to their outermost border.* A change of the same kind occurs in the vessels of the gums when they become soft and spongy; and in ulceration where vessels bleed upon the slightest touch, the blood which escapes containing an unusual abundance of colourless cell-particles.

* Healthy and Diseased Structure, plate 3, figs. 6 and 7.

It is not necessary, however, to the prosecution of our present purpose, to determine the question, whether, and to what extent, lymph particles are generated, as in a blastema, in the effused fluid *outside* the vessels; or whether, and to what extent, they accumulate *on their inside* by separation from the blood within. We hold to our conclusions upon this point; and the facts upon which they are based have elsewhere been discussed. It is sufficient that it be granted that cell particles surround and invest the coats of established vessels before new vessels appear.

The inquiry proposed, then, is with respect to the agents which effect the alterations in the older vessels necessary for the establishment of new vascular lymph-growth, and to the opening out of communications between coherent and tough-walled vessels (those of areolar tissue, for example), and the soft, inelastic new ones (those of repair and inflammation, of lymph foci and granulations). The evidence required in the investigation has already, to a great extent, been made known.

In the present state of opinion, however, we begin with two preliminary propositions, which may be safely affirmed—1. That new blood-vessels, traversing freshly-accumulated lymph, can make their appearance only after some change (or opening) has been made in the coats of the pre-established vessels; 2. That wherever lymph-particles are accumulated, there some species of vital action, of growth, nutrition, secretion, or absorption, is going on.

In the first period of repair, the action is from blood to the texture: there is effusion, lymph-particles accumulate, new blood-vessels and embryoniform growths appear. There is *deposition* and swelling. In the second stage of repair, the continued accumulation of lymph-particles ceases, cell-growth is arrested, a great many of the new vessels disappear, fibrous consolidation ensues, and redundant material is removed. There is *absorption*, and swelling subsides. Here are not simply two stages or two periods of one thing, but two distinct things. At first there is clearly an assemblage of matter and forces incompatible with the welfare of established forms, which, considered in themselves, without reference to what may ultimately appear, constitute no

reparative process at all, quite the contrary: the action observed during the first four or six days, of a process of repair, by *simple continuation*, becomes morbid. The truly reparative part of the process commences, not whilst lymph-growth is in progress, but when it ceases; when the specific type, the fibrous form, of the containing texture of the blood appears. Such being the case, the first period of repair giving birth to unnatural growth, is morbid; and therefore, whatever may be concluded from our inquiry, applies not only to the first period of repair, but also to inflammation. Forasmuch as there does not appear any necessity for assuming a difference in the forces in operation, or in the agents employed in the one and in the other.

Now, *deposition* and *absorption*, growth and destruction, cannot be supposed in progress together, at the same spot, and at the same time, if we speak of the same matter or the same thing; but with respect to two distinct things, there are numerous facts in the economy of the living body—physiological and pathological,—proving that these two actions may be and are concurrent. The alimentary mucous membrane is both an absorbing and an excreting surface—so is the skin. There are times when the elements of food are passing into the circulation from the intestine, concurrently with elements of secretion which are passing out from it. The influence of cantharides, from a blister-plaster, is frequently exercised through the medium of absorption, upon the urinary organs, at the time when there is a copious discharge or effusion from the vessels of the absorbing surface. One species of matter deposited or accumulating, another absorbed or taken away. Many other medicinal substances are well known to be absorbed and carried away in the circulating fluid under similar conditions. The substance of a necrosed bone is in part absorbed and taken away whilst new bone is forming. In the lung, blood absorbs from the air elements which renovate its properties, and at the same time gives off a vaporous exhalation, incompatible with its arterial character and constitution. All these we conceive to be examples of the concurrence of absorption and deposition.

But the phenomena which come

nearest to those, the nature and agents of which we would fain discover, are comprehended under the terms abscess and ulceration. In an abscess there is plainly absorption of the surrounding tissues at the time pus is accumulating; and in ulcers the pre-established textures disappear, whilst discharges are flowing away. In an abscess there is tumor or swelling, not because deposition or the generation of cell-forms is the sole phenomenon, but because the new matter being confined, its accumulation forms the most prominent appearance; in ulceration the new matter is not confined, but being too incoherent to retain a form, it falls away and is discharged, whereupon the loss and disintegration of the original texture becomes the most striking effect. The appearances, therefore, are widely different; but in both the same two physiological actions are concurrent, cell-particles accumulating, and pre-established forms disappearing. When a deep abscess makes its way to the surface and bursts, not only the skin, but multitudes of the blood-vessels of the skin, become gradually thinner and thinner, until at length their continuity is broken without hæmorrhage. Such a phenomenon as this cannot be referred to the action of absorbent vessels brought into play by the influence of pressure, for this must be equal on all sides of the abscess, whereas absorption of established textures, and obliteration of blood-vessels, is determined chiefly in one direction, that which is shortest to the nearest surface and safest for the patient. Again, when ulceration is destroying the natural textures, it will often sever blood-vessels of considerable size without any bleeding. Loss of blood from ulceration is the exception, and not the rule. Here, then, we have more than a simple concurrence of deposition with absorption; for a provident lymph-growth closes and heals the ends of the dis severed vessels in the midst of an otherwise destructive process. These phenomena bear the stamp of cell-agency; and, as each cell, though a microscopic, is nevertheless a whole or individual organism, so mixed changes occur—deposition and absorption—within microscopic areas, which, by the congregation of cells, are effected with greater celerity. The inference here seems borne out by the fact, that in chronic scrofulous abscess, where ab-

sorption or thinning away of the superjacent integument comes to a stand, the cell-particles it contains are found broken, collapsed, irregular in figure, and evidently effete “unhealthy pus:” whereas in an acute abscess, where the process of absorption of pre-established structure is almost as active as the deposition of the new material, the cell-particles are round, plump, and unruptured, constituting “laudable or healthy pus”—a matter clearly only a short way removed from lymph, and this more by the greater abundance of cell-particles than by any other feature of difference. Arguing from these facts, the accumulation of cell-forms is no bar to the absorption of pre-established textures. On the contrary, the essential phenomenon of inflammation appears to be the appearance of cell-particles, upon and surrounding the coats of the vessels, which displace the fibrous elements. And, in the absence of any more direct proof upon the subject, we must conclude that, where new blood-vessels are about to appear, the coats of the old ones are previously altered, their fibrous elements absorbed or removed; so that they come to partake, and at length to be constituted of, the elements of the lymph-material in which the new vessels will appear; these replacing elements being the accumulated lymph-particles,—and this whether the accumulation has accrued *outside* the vessels by generation, “as in a blastema,” or *inside* by deposition from the blood, or partly by the one process, and partly by the other. By these operations—accumulation of cell-forms and absorption of fibrous-forms—blood-vessels are prepared for the formation of new vascular tissue.

And it is to this change in blood-vessels, when their fibrous coats are infiltrated, and more or less completely supplanted by cell-particles, that we have applied the term *retrograde metamorphosis*, from its analogy to certain changes and transformations well known to prevail in vegetable structure. The containing-texture of the blood, prior to the appearance of new vascular growth, truly receding from its specific or concluded form or quality to its primitive or embryoniform condition; whereupon new blood-vessels form, subject to the same laws and provisions as prevail in the embryo-mass originally. And the readiness or facility

with which this retrogradation occurs, and the speed with which new vessels appear, would seem to constitute no mean part of the evidence of our conclusion, *that blood forms its own containing-texture, bloodvessels being correlatives of the colourless elements of blood.* In the first period of repair we regard this (the inflammatory process) with reference to the second period, when the containing-texture of the blood reassumes its normal form and characters unaided by medical art; but in morbid inflammation we anxiously desire to stop it, from the uncertainty of the extent to which it may go.

Upon this interpretation we have evidence of *two kinds of deposition*, and *two kinds of absorption*; the one characteristic of the first period of repair, the other of the second period of repair, or of the cure of inflammation. In the first, cells accumulate, and the specific form of the containing-texture of the blood disappears: new blood-vessels and new cell-growths arising. In the second, cell forms, cell-growths, and most of the bloodvessels administering to them, disappear, are absorbed or abolished, the specific form of the containing texture of the blood at the same time being re-deposited or restored. Thus we have the clearest proof that can be furnished of antagonistic forces. The welfare or permanence of embryoniform cell-growth excludes the normal fibrous structural type of the containing-texture of the blood:—the welfare or establishment of this, on the other hand, excludes the cell-growth: that is to say, the luxuriance of adventitious cell-growth is destructive of natural forms, the reappearance of natural forms destructive of such cell-growth.

The first period of repair (the establishment of cell or embryoniform growth), is necessary to the second, (the restoration or reappearance of the fibrous type),—in conformity with the laws of original growth; but can be considered as a healing operation only in the same sense that the embryostucture, which may be obliterated by a touch, is a chicken or a man. Results, in all these cases, are coming forward, which at length establish a concluded type. In the meantime, we cannot define the perfect by the qualities of the incomplete, and say that the first period of repair is a healing operation.

It appears, then, that at all periods

of life blood may be determined in unusual quantity to any part of the body upon irritation applied to its containing-texture. This, if the bloodvessels undergo no essential change, is simple congestion, or, to use the technical phrase, *hyperæmia*: it becomes inflammation when cell-forms accumulate, and the coats of the vessels are losing their concluded form. Under various circumstances effusions also take place: these are simple if the blood vessels maintain their normal constitution; but inflammatory, if cell-forms are supplanting fibrous elements.*

Inflammation and organisation are accepted terms, and they comprehend two distinct classes of facts. We refer organisation to an antecedent power or force, and call it "germ-force," "organic life," &c. But, with respect to inflammation, we are not in the same logical position; for we use the word sometimes in the sense of an agent; at others, as merely expressing the phenomena. Thus, we are apt to say that inflammation does this or that, and also that it consists in this or that. Now it is perfectly allowable, in a philosophical discussion of the subject, if we refer organisation to an antecedent force, to do the same for that class of phenomena comprehended under the term inflammation.†

But we confine ourselves to a simple statement of the phenomena. The elements of blood, under normal circumstances, are subject to the forces which are operative in organisation and natural growth; but in inflammation, or the first period of repair, they emerge from this subserviency, and establish embryonic, and therefore retrograde forms of growth. These, in a process of repair, are limited in extent and continuance, conforming in due time to the laws of natural growth: but, in inflammatory and scrofulous disease, they spread and are persistent, prevailing over the forces which govern and sustain the concluded type, or the fibrous form of the containing-texture of the blood.

In inflammation, abortive repair, and scrofulous disease, there is ample room for speculation whether the inherent organising force is too weak or inade-

* Illustrative facts are detailed in our work *On Healthy and Diseased Structure*, p. 284.

† Upon this point see Whewell "On the Inductive Sciences," quoted p. 90, *supra*.

quate in some absolute sense, or relatively only to an increased energy on the part of the elements of blood. This is the question substantially at issue when we speak of asthenic inflammation, poverty of blood, and scrofulous diathesis. Chemical investigations here come in aid; but we think it must be allowed that variations in the constituents of blood and the secretions, within the limits of health, are too wide for chemical analysis yet to be our guide in practical medicine.

As regards the term retrograde metamorphosis.—In the “scale of organisation,” animal bodies which have bones rank higher than those with only fibrous textures, and these higher than the corpuscular or cell-textures, which are esteemed the lowest. But the elements of the lowest forms of organisation—viz., cells—rank higher in the *scale of vitality* than any element of fibrous, tendinous, or osseous tissue. Every cell is a whole organism; whereas bones, tendons, fibrous textures, and blood-vessels, can be parts only of a whole. In the highest, and in all the intermediate forms of living beings between the lowest and the highest, the particular substance of the secreting organs—the liver, kidneys, &c., the most energetic portions of the brain and of the blood—consist of cell-organisms; and it is evident, from all the facts of the case, that a broad distinction must be preserved between elements of *form* and elements of *vital action*. The former have the lowest—the latter the highest vitality. Bones, fibrous-textures, skin, and vascular-tissue, clearly “degenerate” when they become supplanted by particles of lymph or pus, inasmuch as their form and organisation are lost. But, on the other hand, the replacing matter, soft and incoherent though it is, can be said to be “degraded” only in a certain sense; for every corpuscle *which is effective* in the lymph or pus has, far more “vital energy” than any portion of the ministerial textures they supplant. Hence the term retrograde metamorphosis refers, not to vital properties, but to condition or form. And be it remembered, that “life is made manifest to us, not by form, but by acts. It cannot, therefore, be considered as an attribute of uniform character or unchanging intensity.” And, judging of the intensity of life by the prominence

of the effects, there is far more of life in an acute abscess or ulcer than in the natural structures they supplant, but it is not of the kind or co-ordinated to the species required. The gradual accumulation of pus in spite of many opposing forces of a physical kind—its determination, as it were, to push aside and thin away opposing obstacles—are phenomena of life: and we witness here an exhibition of forces analogous to those which enable the tender plumule of the plant to upturn a giant clod of earth. The organised textures reproducible by the process of repair, and which appear in the products of a cured inflammation or scrofulous disease, hold no very high place in the acts of life. Bones are merely crutches for support, and are notoriously modelled and channelled by the softer tissues; tendons are simply cords attaching the motor-tissue to the bones; and vascular-tissue is subordinate in natural, and even in unnatural growth, to the particular substance—the parenchyma of the organ. For if the brain-substance be malformed or deficient, its vascular-tissue and its bones are generally malformed and deficient likewise; and, in monstrous growth, if brain-substance be unnaturally evolved, exceeding the specific bulk, its vascular-tissue is unnaturally expanded also; and, moreover, the bones of the skull are abnormally expanded, and their number, too, is much increased.

Thus we return to the high significance of embryological researches, where sentient and motor forms are the first moulded; and being so, blood appears. After these follow the containing-texture of the blood; and, lastly, tendinous and osseous structures;—all in subservience to the leading forms, and these last again subservient to the “power” inherent in the “germ.” If this be crippled in the evolution of sentient-matter, vascular-tissue, tendons, and bones, conform to the deficiency. On the other hand, if the nervous centre luxuriate in growth, vascular-tissue and bone luxuriate with it. If the “germ-power” be so much blighted that the leading forms (spinal cord and cerebral ganglia) be not moulded, blood does not appear. Blood not appearing, there can be no vascular tissue; and without this there can be neither tendons nor bone.

It may be objected to the conclusion that bone is a metamorphosed form of

vascular-tissue, that if either a wing or a leg of the embryo-chick, when first budding forth on the fifth day, or either of the extremities of the human embryo, when these are not much larger than a mustard-seed, be gently compressed between two slips of glass, and examined with a microscope, all the bones will be seen symmetrically arranged and moulded to their proper shape before any blood or blood-vessels can be seen near them: and, in our figs. i. and ii., p. 194, the dorsal plates are shown as existing at the fortieth and fiftieth hour of incubation. These facts, which might be supposed to militate against, do in truth serve to establish our conclusions. For the substance thus shaped and moulded is a *germ-mass*, entirely composed of soft corpuscles or cells. It is not bone: there is nothing hard—nothing resembling bone. Bone-substance does not appear until some time after this primary form has been permeated in all directions by blood and vascular tissue. So that here, though the form and outline of the future member is cast before blood circulates through it, still *ossification* does not commence except through the agency of the containing-texture of the blood.

FATAL HÆMORRHAGE FROM THE UMBILICUS IN NEW-BORN CHILDREN.

In two cases observed by Dr. Bowditch the children died of hemorrhage from the navel (on the twentieth and fourteenth days after birth). They were of both sexes; while males, according to authors upon the hemorrhagic tendency, are more liable than females. In both cases the cord came off quite well, and without external injury; one on the third, the other on the fifth day after the hemorrhage commenced. In both, the parts seemed entirely cured, and presented no discharge for several days before the fatal oozing took place. In both, all local applications seemed, in a very short time, to excite rather than to check the disease. In both, very violent surgical operations were resorted to without the least benefit. Death took place in one on the third, in the other on the sixth day after attack. One had white dejections from birth; both had purpuric extravasations and bloody dejections at last. At the autopsy of one, disease of the liver and non-coagulated blood were found; no opening or apparent disease about the navel or vessels leading thereto was found.—*American Journal of Medical Sciences*, Jan. 1850.

ON NARCOTISM BY THE INHALATION OF VAPOURS.

BY JOHN SNOW, M.D.

[Continued from last vol. p. 627.]

PART XIV.

Chloroform passes off unchanged from the blood, in the expired air—its detection in the urine—in the dead body—in an amputated limb—Remarks on the process for its detection.

At the end of the last paper, reasons were given for concluding that the effects of narcotic vapours were not due, as some had supposed, to the hydrogen and carbon they contain, combining with the oxygen of the air dissolved in the blood; and evidence was adduced to show that if such combination do take place, this would not explain their narcotic action. It still remained desirable to determine by experiment, if possible, whether these bodies are decomposed in the system, or pass off unchanged in the breath, or in other ways. With this view the following experiment was performed:—

Exp. 54.—Ten minims of chloroform were put into a hydrogen balloon, holding 300 cubic inches. The balloon was filled up with air, which I breathed backwards and forwards, in the way in which nitrous oxide gas is taken, for probably about two minutes. The word probably is used, because, after observing the watch for a minute and a half, I lost the recollection of what I was doing, and on recovering so as to observe the watch again, I found that another minute had elapsed, and that I had carefully lain aside the balloon in the meantime. Half a minute after this, and three minutes after beginning to inhale, I commenced to pass the expired air through a tube of hard glass, which was placed in readiness in a charcoal fire. To the further end of the tube were fitted other tubes connecting it with two Woulfe's bottles, each containing a solution of nitrate of silver. The expired air was taken in by the nostrils and breathed out by the mouth, passing first through the red hot tube, and afterwards through the solutions of nitrate of silver. This process was continued for four minutes.

The solution was rendered turbid, more especially that in the first bottle; being at first white, but shortly afterwards of a dark violet colour. At the end of twenty-five minutes from the inhalation, and when scarcely any appreciable effect of the chloroform remained on the feelings, I again breathed the expired air through the red-hot tube, the Woolfe's bottles having been removed, and a small tube moistened inside with solution of nitrate of silver having been attached. A slight precipitate of chloride of silver immediately appeared in the tube. The precipitate in the Woolfe's bottles having been washed and dried on the filter, was found to weigh 1·2 grain.

I have on other occasions, after inhaling chloroform, made the expired air to pass at once through a solution of nitrate of silver without the intervention of the red-hot tube, when not the least precipitate was occasioned; consequently, the chlorine which combined with the silver in the above experiment was the result of the decomposition of chloroform in the hot tube, and not in the circulation. As upwards of half a minute was allowed to elapse, during which several inspirations were taken between the conclusion of the inhalation and commencing to breathe through the tube, the lungs must have been completely emptied of the air taken from the balloon, and the vapour of chloroform must consequently have been exhaled from the blood. The further part of the experiment, performed twenty minutes later, more strongly proves this, and also shows that chloroform continues to be exhaled as long as any appreciable effects of it remain.

If all the chlorine of the chloroform united with the silver, the quantity of chloride obtained in four minutes, in the above experiment—viz. 1·2 grain, would indicate only 0·476 grain of chloroform. But I have found that on passing the vapour of a known quantity of chloroform through a red-hot tube, only about one-third of the chlorine is liberated, chiefly in the form of hydrochloric acid gas, and combines with the silver, as will be more fully explained further on: consequently, the above quantity of chloride of silver may be taken to indicate 1·428, or nearly a grain and a half of chloroform. It would not be easy to continue to test

for the whole of the vapour exhaled by the breath. Indeed, breathing through the tubes and liquids for four minutes, in the above experiment, was attended with some inconvenience. But when it is considered that part of the chloroform used must have remained in the balloon, that a further part must have been exhaled before beginning to breathe through the red-hot tube, and that the vapour was still being exhaled twenty-five minutes after the inhalation, the experiment must help to confirm the view that by far the greater part of the chloroform inhaled is exhaled again by the breath.

It is probable that a small portion of chloroform passes out by other channels than that of the expired air: the latter, however, offers such a ready and expeditious outlet, that the quantity excreted in any other way is, most likely, very minute. I have on four occasions examined urine passed after the inhalation of chloroform, by boiling it in a flask, and passing the vapour, first through a red-hot tube, and afterwards through a tube moistened inside with solution of nitrate of silver, and I only on one occasion obtained a very slight precipitate of chloride of silver.

The presence of chloroform can be detected in portions of the body removed by the surgeon, when the patient is under its influence, and in the bodies of animals killed by it. And as this part of the subject is interesting in a medico-legal as well as in a physiological point of view, I shall enter a little more minutely into the account of it than I might otherwise have done. In the *Journal de Chimie Médicale* for March, 1849, a process for the detection of chloroform in the blood is described in the following terms:—"In order to recognise the presence of chloroform in the blood, we take advantage of the property which this body possesses of being decomposed at a red heat, in giving rise to chlorine and hydrochloric acid. In order to perform the operation, it is sufficient to boil an ounce of blood for some time in a glass flask over the water bath. The vapour must pass through a tube heated to redness at one part, and of which the extremity is smeared interiorly with a mixture of iodide of potassium and paste of starch. A strip of paper moistened with the same mixture may also be put into the tube. If any chlorine be produced by

the decomposition of chloroform, the strip of paper will be turned blue. In this way one part of chloroform in 10,000 of blood may be discovered." It is not stated in this article whether the chloroform detected had entered the blood during life, or had been added after its removal, though the former was probably meant.

In employing this process I substituted solution of nitrate of silver for the starch and iodine test, considering that to obtain some of the chlorine as chloride of silver would be more satisfactory, in a medico-legal point of view, than merely showing the presence of something which decomposes the iodide of potassium. I find, also, that the nitrate of silver possesses other decided advantages. In the first place, it is a much more certain and delicate test. The iodine test is not acted on by hydrochloric acid, but only by the free chlorine, very little of which is produced by passing the vapour of chloroform through a red-hot tube, and that not constantly. Again, if there be a trace of chlorine to set free a little of the iodine, a little warm vapour, which is very apt to rush through the tube, whilst it does not affect the chloride of silver, may either prevent the blue colour of iodide of starch being developed, or suddenly discharge it, as I have seen. And lastly, the nitrate of silver test allows of a quantitative analysis being made, whilst the other does not admit of it. Dr. Alfred Taylor has, however, suggested to me to combine the two tests with a third one, by introducing a slip of starch paper moistened with solution of iodide of potassium, and also a slip of blue litmus paper, into another part of the tube, where it is not wet with the nitrate of silver. Used in this way, these additional tests may tend to confirm the evidence, and to meet objections that might possibly be made to the nitrate of silver test when used alone.

Before relating the experiments in which the presence of chloroform was detected in the body, it will be preferable to give some account of the decomposition which takes place when the vapour of that substance is passed through a red-hot tube. Soubeiran, when treating, in 1831,* of the body afterwards named chloroform, said, that

on passing it, in the form of vapour, through a tube of porcelain filled with small fragments of porcelain, and made red-hot, that a good deal of charcoal is deposited, and that a gas is produced formed almost entirely of hydrochloric acid; and that there is found besides a very small quantity of chlorine and of an inflammable gas. He added, that, unless the pieces of porcelain are so arranged in the tube as to delay the passage of the vapour, without obstructing it too much, there is more chlorine liberated, and a substance left in the tube which stains paper like an oil. Liebig† says of chloroform, "when its vapour is passed through a red-hot tube it is decomposed into carbon, hydrochloric acid, and a crystalline body which appears in long white needles." On another occasion† he says that this crystalline body is probably the perchloride of carbon discovered by Mr. Faraday.

I performed the following experiments with a view more particularly to ascertain whether any appreciable quantity of free chlorine is produced during the decomposition of chloroform at a red heat:—

a. Ten grains of chloroform were put into a dry retort, made out of a small green glass tube, and capable of holding only a drachm. The retort was heated gradually in the water bath. Its beak was kept red-hot by the flame of a spirit lamp, and communicated with two Woollf's bottles, containing solution of nitrate of silver. Charcoal was deposited in the beak of the retort at the part where it was red-hot: half an inch from this part, on each side, there was a copious deposit of long, white, needle-shaped crystals, and, after a time, a reddish-brown oily-looking liquid appeared. The precipitate of chloride of silver, which was found almost exclusively in the first bottle, weighed, after being washed and thoroughly dried, 12·5 grains.

b. Ten grains of chloroform were put into a similar retort and treated in the same way, except that the beak of the retort opened under a receiver in the mercurial trough. The deposits in the tube of the retort were the same as before, and 0·15 cubic inches of gaseous matter were obtained in the receiver.

* *Annales de Chimie et de Physique*, t. xlviii. p. 135.

* *Turner's Chemistry*, 8th edit. p. 1009.

† *Annales de Chimie*, t. xlix.

The tenth of a cubic inch of water being passed through the mercury, 8.5 cubic inches of the gas were absorbed by it. Solution of potash absorbed one-tenth of a cubic inch more, and the remainder consisted almost, or entirely, of air expelled from the retort.

a. Ten grains of chloroform were treated in the same way as before, the beak of the small retort communicating with two Woolfe's bottles, the first of which contained only thirty minims of distilled water, and the second some solution of nitrate of silver. A very slight cloudiness was merely produced in this solution in the second bottle. The water in the first bottle being added, at the end of the process, to a solution of nitrate of silver, and the precipitate occasioned being boiled in nitric acid, washed, and thoroughly dried, was found to weigh 11.45 grains.

If one of the three atoms of chlorine which were contained in the chloroform were to combine with the single atom of hydrogen, the hydrochloric acid thus produced from ten grains would weigh 3.04 grains, and would suffice to form 12.08 grains of chloride of silver. In experiment *a*, the chloride of silver obtained exceeded this by a very little. In experiment *b*, any chlorine which might be developed would be absorbed by the mercury, and the 8.5 cubic inches of gas absorbed by the small quantity of water must have consisted of hydrochloric acid. The weight of it would be 3.24 grains—a very little more than ought by theory to result from the combination of one of the atoms of chlorine with the hydrogen of the formyle; and it would combine to form 12.7 grains of chloride of silver. In experiment *c*, the thirty minims of water, whilst they absorbed the hydrochloric acid gas, could absorb but a very minute quantity of chlorine, certainly less than the tenth of a grain, and consequently if a greater amount of chlorine than this had been evolved it must have passed on to the second bottle, and there caused a precipitate of chloride of silver. On precipitating with nitrate of silver, it will be observed that the quantity of chloride obtained was very nearly that which ought to be formed by the hydrochloric acid produced as suggested above. These experiments, then, tend to show, that if chlorine be produced by passing the vapour of chloroform through a red-hot tube, it must be in extremely small

quantity, and that consequently the proper tests to employ are those which indicate the presence of hydrochloric acid.

The following is a brief account of the experiments for the detection of chloroform in the body:—

Exp. 55.—Two kittens about a fortnight old were placed in a glass jar holding 120 cubic inches. Twelve minims of chloroform were dropped on a piece of blotting paper in the jar, and it was closed. In two minutes the kittens were both insensible, and in two minutes more one of them had ceased to breathe; the other continued to breathe feebly and irregularly for six minutes longer. On the following day one of the kittens was opened: there was no odour of chloroform perceptible in this, any more than in the numerous other animals that I have killed with it.

a. The lungs, liver, and kidneys of this kitten were placed in a wide-mouthed glass flask with two or three drachms of water. The flask was placed in the water bath, to which (common salt not being at hand) was added a little chloride of calcium, to increase the temperature somewhat. A tube passing through the cork of the flask was connected with one of hard glass, which was kept red-hot in the flame of a spirit lamp, and to the end of the latter tube was attached one wetted inside with solution of nitrate of silver. About the time that the contents of the flask began to boil, a white curdy precipitate appeared in the latter tube. This precipitate was rendered dark-coloured by the light. It was insoluble in nitric acid, and very soluble in ammonia.

b. Two days after the death of the kittens, the lungs, heart, liver, and kidneys of the other animal were treated in a similar manner. Soon after the water in the flask began to boil, a precipitate of chloride of silver appeared in the tube.

c. Three days after their death, the brains of both kittens were put into a flask without any water, and heated in the chloride of calcium bath, as the other parts had been. On this occasion the tube moistened with solution of nitrate of silver ended in a Woolfe's bottle containing a few minims of the same solution. By the time that the liquid which had exuded from the brains began to boil, a precipitate began to appear in the tube. In a short time there was a slight cloudiness in the bottle.

The brains were kept boiling in their own serosity for an hour. On the following day heat was again applied to the flask containing the brains which had not been removed; the tube and Woolfe's bottle having, however, been cleaned and supplied with a fresh solution of nitrate of silver. Not the slightest precipitate was obtained on this occasion, although the brains were kept boiling for two hours.

d. Five days after its death one of the kittens was skinned, and the flesh of the limbs, together with the greater part of that of the body and neck, was stripped off and put into the flask and treated as before, with the exception that, instead of the solution of nitrate of silver, a slip of paper moistened with a mixture of starch and solution of iodide of potassium was placed in the farther end of the tube. After the flesh had been made to boil for a little time in its own juice, a small part of the paper was turned blue.

e. Six days after its death the skin of the other kitten was removed, and its flesh put into a flask and treated as above; on this occasion, solution of nitrate of silver being used as the test. The serosity of the flesh had scarcely begun to boil, when a precipitate of chloride of silver began to appear, and was soon as copious as on any previous occasion, both in the tube and Woolfe's bottle. At this time the intestines of the kittens were beginning to be offensive, although the flesh used in the experiment was not at all decomposed. The bodies had lain on a table since the time of death, at the beginning of last May, when the temperature was cool. From the size of the animals, the quantity of chloroform inhaled by each was considerably less than a grain.

To try the delicacy of the above process, a grain of chloroform was dissolved in a hundred drops of rectified spirit, and one drop of this solution was dropped into a flask containing a thousand grains of water. On treating this as above described, a distinct precipitate of chloride of silver was obtained in the tube, thus indicating the presence of the hundredth part of a grain of chloroform in a thousand grains of water.

Exp. 56.—On May 9, some portions of muscle, nearly sufficient to fill a three-ounce bottle, were taken from the calf of the leg of a little boy, about five years old, which had just been amputated by Mr. P. Hewett, under the influence of

chloroform, in St. George's Hospital. About four hours afterwards the pieces of muscle were put into a flask, and treated as before described, solution of nitrate of silver being the test applied. When the liquid exuding from the muscle had been boiling for about ten minutes the precipitate began to appear, and was soon very distinct.

On July 2d, I assisted Dr. Taylor, in the Laboratory of Guy's Hospital, in applying this process to a little of the blood of a man whose death had been occasioned by chloroform, six days previously. The blood, which had been kept in a stoppered bottle, measured six and a half drachms, was of a dark red colour, fluid, but rather thick, and did not smell offensive. It was put into a clean Florence oil flask, from which a tube proceeded which was made red-hot, and a further tube moistened inside with solution of nitrate of silver. The flask was heated in the water bath, to which, after a time, common salt was added. The process was continued for twenty minutes or more, and although a slight cloudiness was observed in the tube, no distinct precipitate of chloride of silver was obtained. It should be remarked that this small quantity of blood must necessarily have been exposed to the air, before it was put into the bottle, by which means it would lose a part of its chloroform.

At the suggestion of Dr. Taylor, some chloroform (about 8 drops) was put into a flask with an ounce of water, and in the further tube were placed, first, a slip of starch paper moistened with solution of iodide of potassium; next, a slip of blue litmus paper, and the distal extremity of the tube was wetted inside with solution of nitrate of silver. The intermediate tube being made red-hot, as soon as heat was applied to the water bath, the two pieces of paper and the solution of nitrate of silver began to be affected, almost simultaneously: the starch paper being rapidly rendered very blue, the change of colour beginning at one end and travelling rapidly along it.

On the same occasion, in order to try the delicacy of these tests, a drop of chloroform, which is equal to the third of a grain, was agitated in a minim measure with fifty minims of alcohol. Five minims of this solution were added to an ounce of water in a flask, which

would consequently contain the thirtieth part of a grain of chloroform. A fresh tube being attached, containing the three tests before employed, and the flask being heated in the water bath, a decided effect was, in a little time, produced on all the tests. The starch paper was rendered blue; the litmus was turned red; and a very distinct precipitate was obtained in the solution of nitrate of silver.

EXP. 57.—July 13: Half a drachm of chloroform was diffused through a jar holding 870 cubic inches, and a kitten, weighing a little over thirteen ounces, was put in. In two minutes it was quite insensible, and at the end of ten minutes it died. On the 15th the kitten was opened, and the viscera of the chest, the liver, and the brain, weighing together nearly two ounces, were put into a flask and heated in the salt water bath. A tube coming from the flask was kept red-hot, and a further tube contained a slip of starch and iodide of potassium paper, and a slip of blue litmus, and terminated near the bottom of a Woolfe's bottle containing a few minims of solution of nitrate of silver. At the early part of the process, the edge of the starch paper seemed to be slightly changing colour, but after a little time no change of colour could again be observed in it. The blue litmus was very soon reddened, and the solution of nitrate of silver began to be turbid, and the turbidity increased for some time. The viscera were kept boiling in their serosity for half an hour.

On the following day other six ounces of the same kitten were put into the same flask; the intestines, skin, and larger bones being only left. Fresh starch paper was put into the tube which terminated in the bottle containing the same solution of nitrate of silver. After a little time the starch paper was decidedly darkened, at the corner nearest the flask, but only to a limited extent, which did not increase. The parts were kept boiling in their serosity for two hours, when the process was ended by the breaking of the tube at the part where it was red-hot, owing to a little condensed steam being projected against it. At the same moment the limited blueness of the starch paper was discharged. The tube being left lying on the table, it was found next day that the starch paper was very blue throughout its entire extent, from what cause I do

not know. The precipitate of chloride of silver was separated by filtration, and but for an accident would have been dried and weighed. There appeared to be not less than the twentieth part of a grain of it.

There is no deposit of carbon in the red-hot part of the tube in this process, as the apparatus always contains sufficient air for the formation of the carbon into carbonic acid. The white needle-formed crystals previously mentioned are deposited, but not in sufficient quantity to be of service as a test. It is desirable to make the tubes proceeding from the flask incline a little upwards, so that the vapour which is condensed before reaching the red-hot part may flow back again. I consider that the solid organs of the body should be taken for analysis, in preference to the blood in a separate state, as that contained in the minute vessels is protected from the action of the air. The parts should be cut in pieces, and put into the flask, without any addition. The stomach should not be selected for examination by the above process, as the gastric juice contains a minute quantity of free hydrochloric acid, and hence the evidence would be liable to objection. The intestines also do not seem suitable parts for examination, as the sulphuretted hydrogen they might contain would interfere, more or less, with the tests. In other respects it matters little what part of the body be used, further than that the most vascular parts are the best. As regards a quantitative analysis, it results from some of the experiments, detailed in an early part of these papers,* that, in a case of death from chloroform, a quarter of a pound of any organ of average vascularity would contain about the twelfth part of a grain, which, if the whole of it were separated and decomposed, would produce about the tenth of a grain of chloride of silver.

The process above described does not prove the presence of chloroform itself, but only that of a volatile compound containing chlorine. In this respect it resembles the processes for the detection of arsenious acid and corrosive sublimate in the tissues, which prove only the presence of a compound of arsenic, or of mercury. The only compounds containing chlorine which are volatile at

* MED. GAZ., vol. xlii. p. 415.

the heat of boiling water, are substances such as chloride of ethyle, Dutch liquid, and some others, which resemble chloroform in their effects, but are none of them in common use. In order to be quite certain that the precipitate is no other salt of silver than the chloride, besides the tests of ammonia and nitric acid, solution of potash might be added to another portion of it, as recommended by Dr. Taylor, in treating of hydrochloric acid.* Potash does not change the chloride of silver without heat.

With these limitations and precautions the process is, I believe, liable to no fallacy. There are chlorides in the body, but they cannot be decomposed, except at a high temperature, and not till the part under examination should become dry, which, in the method here described, could not take place in the most protracted examination. Besides, I have made several examinations of parts not containing chloroform without meeting with anything that produced the slightest effect on the nitrate of silver, or on the starch or litmus test. The bodies of two kittens killed with the vapour of ether were submitted to the process, by portions at a time, which were made to boil in their own serosity for an hour or two, but not the least effect was produced on any of these tests. Hearing, in the beginning of May last, that chloroform was suspected, by some of the coroner's jury, to have been used in the case of a woman who was found dead, under mysterious circumstances, in the Wandsworth Road, I applied to Mr. John Parrott, who was polite enough to send me some portions of the body, including part of the brain and liver. They had been kept in a covered jar from the time they were removed from the body. The chemical examination commenced four days after death, whilst the parts were fresh, and although very carefully conducted, not the least effect was produced, either on the nitrate of silver or starch and iodine test.

NOTES ON THE STRUCTURE, &c. OF TEETH.

BY C. SPENCE BATE.

Dentine.

I. THE resemblance of the tooth-substance, or dentine, with that of true bone, has long been a subject of discussion. The opinion of a supposed analogy has been based upon microscopic research among various characters of teeth belonging to different tribes of animals.

Chemistry also has been made use of in order to assist towards a correct conclusion; and analysis shows that the difference between the two substances exists but in a matter of a relative quantity of the parts respectively of which they are both composed.

Whenever there is any difficulty in defining the character of a structure when complete, the surest means to obtain the knowledge is to study its progressive development and formation, by tracing the analogy which it holds to that of the development of other structures among which it is presumed to hold a place; that, if we cannot interpret the sign when complete, we may if we watch their putting together.

II. In the development of bone we find cells generated in temporary cartilage,—a homogeneous non-vascular plasma, which obtain their calcareous contents by secretion from the blood-vessels which ramify and inosculate with one another in that part of the structure which has already been converted into bone.

III. But if we examine the manner in which the tooth is developed from the pulp, we find that a somewhat different process is pursued.

There is no true temporary cartilage to form the bone of tooth; but this substance is represented by the pulp, which only approaches to its character in a limited degree.

IV. From the very first formation of the papilla, the pulp is a highly vascular organ (Fig. 1). Blood-vessels, which supply it with the means of growth and development, pass into the centre of its own substance. The growth of the pulp continues until it has reached the diameter of the future tooth when fully developed: having ex-

tended to its furthest limits, ossification commences, and not before.

FIG. 1.

FIG. 1. Pulp of human permanent under incisor at birth, showing its vascularity.

This takes place at the apex, and proceeds to extend over the periphery of the pulp in the character of a scale; thus differing from the development of bone, which ossifies first towards the deepest part, or centre of the cartilage.

Thus we see that the mass of the pulp is not converted directly by ossification into bone, but that it undergoes a transformation previous to this change, which transformation takes place normally only at the periphery.

V. If we examine a section of the pulp of a tooth cut horizontally, we find that its substance is not composed of isolated cells in a homogeneous plasma, like temporary cartilage, but that, there ramifies throughout the mass a cellular tissue, areolar in character, which sometimes, if not always, ossifies with the rest of the pulp (*vide* fig. 8). But if we make a section of the same tooth, which shall embrace the surface of the pulp at that point which approaches nearest to where conversion into ivory has already taken place, we observe that the character has changed: the cells unite together in a very uniform character, so as to form a layer without any inter-cellular substance.

If we trace this layer of cells towards the dentine deposited, we cannot define the exact point at which ossification commences, so gradual is the transition; but we may shortly observe that between the cells an opacity is visible. By tracing these transition-cells still further into the bone, we perceive distinct spots, which in some instances

may be seen to be hollow spaces admitting light. Still deeper in the dentine we find that these spots become united to lines of a less diameter than their own: these lines are the commencement of the tubes of Retzius, Owen, and Tomes,—the beccated fibres of Nasmyth.

Having obtained two sections,—one of which was horizontal with the pulp, the other at right angles, or rather diagonal with the structure of dentine,—our next object is to obtain one which shall be in a direction corresponding with both the dentine and the pulp. To procure this, the better way is to make a section of a tooth at the apex, taking care not to dislocate the pulp from its connection with the ivory. After many attempts, the one from which the accompanying illustration is taken was obtained from a lamb at birth.

FIG. 2.*

FIG. 2. Pulp in connection with dentine, demonstrating tubercular structure of loop, from lamb at birth.

In this section the blood-vessels may be traced to the confines of the pulp, where they form loops, from the extremity of which, processes extend into the substance of the dentine for a considerable distance, thereby demonstrating the original tubular character of the fibres in dentine.†

* The sketch from which this cut is taken was made as carefully as the author was capable; and the fragment of tooth from which it was drawn is still preserved.

† It is stated in the *Annals of Natural History* for April, that Professor Owen lately, in dissecting an elephant which died at the Zoological Gardens, fully verified the idea of the tubular structure of ivory, inasmuch that he, in removing the pulp from its connection with the dentine, distinctly saw processes of the pulp pass into the tubes in the ivory.

VI. The cells of which the pulp is mostly composed are various in size and form, but assume a uniformity in both as they approach the external surface of the pulp, where they are endowed with the power of secreting the bone-earth, which, upon having fulfilled their office in becoming charged with calcareous matter, the dentine may be said to be completed; as a large tusk of ivory is but a repetition of separate calcareous scales or layers, the demarcation of which may be observed by the naked eye in the rings which are seen upon a section of an elephant's or hippopotamus's tooth, when cut in two at right angles with its length, and which bear a resemblance to the rings of annual deposit in trees of exogenous growth.

These layers may be more distinctly observed in a thin section fractured forcibly from the mass, in which they may be seen to succeed each other in an imbricated manner.

These layers continue to be deposited until the whole pulp has been converted into dentine, which, in some kinds of teeth, is completed within a definite period, whilst in others it is extended over an unlimited space.

In man, and all animals in which the fangs of the teeth decrease towards a point, the growth of the tooth is limited, although conversion of the pulp into dentine continues slowly to be carried on during probably the greater portion of existence; but this is wholly within the tooth: the pulp canal gradually decreases, and in old age approaches obliteration.

But in those animals in which the pulp lies in an open fossa, the tooth continues more or less slowly to increase in length,—a supply set up at one extremity to meet a demand at the opposite, in the waste of dentine occasioned by mastication.

This is well known to be the case in all the Edentata class of mammals; but it is also the case in some of the Rodentia. This is well exemplified in the case of a hare shot in this neighbourhood (Swansea). It by some accident had long since lost the under incisor teeth; consequently, those of the superior jaw increased in length to such an extent as almost to complete a circle, which it probably would have done had the animal not been taken until a few years later.

FIG. 3.*

FIG. 3. Hare (*Lepus timidus*), the superior incisor teeth of which had grown to an extraordinary length; (a) tooth removed from the socket.

Neither can this be confounded with the prolongation of teeth such as we find take place in the human mouth

upon the loss of an antagonistic tooth, which is not growth of bone, but an elevation of the tooth in its own socket, from which it generally, by an effort of nature, is ultimately expelled.

VII. The cells of the pulp pass into

* This animal was shot a year or two since by Mr. Gage, and the skull is now in the cabinet of L. Dillwyn, Esq.

dentine, and by their transition compress the vascular system into a smaller area: the bloodvessels which first nourished the spot now hardening, are reduced, so that they send only a branch or process, which, upon dentine being further developed, becomes still more reduced in diameter, so as to preclude the passage of a single blood-disc. The remains of the vessel ossify, and become the parietes of the tubes.

There is another fact, besides those already mentioned, which shows that the original diameter of these tubes was much greater. If we take a section of dentine which shall cut the tubes at right angles with their length, we shall observe that a transparent areola surrounds the opaque centre; the circumferences of these areolæ appear to mark the area of the original tubes (*vide* fig. 8).

VIII. If we compare this structure with other animals, we find in fish the same fibres or tubes present; and it is but reasonable to presume that in all cases, whether fish or mammal, the process of their development is the same.

There is among the former a species of dentine termed vascular, or vaso-dentine, in which we lose the fine hair-like tubes, and in their place have large canals. These canals I believe to be the original blood-vessels of the pulp, which latter has become ossified without compressing them into tubuli smaller than their original diameter.

Fig. 4.*

FIG. 4. Dentine, from section of tooth of the Hake (*Gadus maluccius*); (a) natural size.

It is scarcely possible for any one not to be struck with the remarkable similarity between the annexed cut and that of fig. 2; fig. 4 being the ossification of the pulp without compression of

* I picked up the specimen in a jaw stranded upon the sea-shore, and am not an ichthyologist sufficient to identify beyond doubt the genus to which it belongs.

the blood-vessels,—that of fig. 2 the blood-vessels in the pulp previous to ossification.

But a still greater resemblance to the former figure may be seen in those teeth of fish, such as the shark of the extinct genus *Lamna*, wherein an external layer, something approaching true dentine in character, is formed external to the vascular dentine, wherein the tubes may be seen to terminate in the large canals,—the presumed blood-vessels of the pulp previous to ossification,—and which may still continue to be so in this modified form of the tooth-substance.

Fig. 5.

Fig. 5. From fossil tooth found in the Isle of Sheppy.

IX. It is owing to the compression of these canals, which trace the path of the compressed blood-vessels, that the waves in the tubuli known as the primary curves are due: but those which are recognised as the secondary, owe their origin to the bends occasioned by the alternating position of the cells of which the dentine itself is composed.

The relation which they bear to each other may be seen in the two annexed engravings,—the one (fig. 6) being from the pulp of a human deciduous tooth at birth, that of the other* (fig. 7) from the dentine of a permanent human tooth, a

Fig. 6.

Fig. 7.

FIG. 6. Surface of human pulp of a tooth at birth.

FIG. 7. Human dentine, saturated in dilute hydrochloric acid.

* Fig. 7 was suggested in order to verify a similar experiment of Mr. Nasmyth's.

section of which had been saturated for a few hours in dilute hydrochloric acid.

With regard to the baccated character of which Mr. Nasmyth writes, much I think may be attributed to the manner in which his objects were prepared, most having been obtained by violence, some by being pounded in a mortar, others being shavings obtained by the turning lathe. These would most probably produce the appearance such as Mr. Nasmyth has figured, and which he so strongly urges.

But the appearance of a baccated structure may occasionally be due to other causes; as, for instance, should the cells adapt themselves so that the interstices of one row may fall opposite to those in the next, instead of alternating: or, should the secondary curves be partially rubbed away in the preparation of the section, a similar modification would be the result.

X. It must have been noticed by the least accurate observer that these lines are the only opaque markings in dentine, the remainder of the substance being semi transparent. It is also upon this, among other reasons, that Nasmyth has joined issue with Retzius, and others, as to the tubular character of these lines; and it is not without justice that the following argument is made use of in Mr. Nasmyth's posthumous work, that "Retzius and his followers remark that, when a section of a tooth, made transversely to the direction of the fibres, is viewed upon a dark ground, a white spot is perceptible in the area of each of the so called tubes. Now this is the fact, but the inference to be drawn from it is directly opposed to that which Retzius endeavours to establish; for it is quite evident that if we view an object pierced by an aperture, instead of being white it should be black, while the contrary proves that it is no hole at all."

XI. I wish now to draw attention to a peculiar appearance often met with in the fangs of individual teeth, when the periosteum has been the seat of an inflammatory action, chronic in character, and of long standing. The appearance to which I allude must have fallen under the notice of all who study the diseases of the teeth. The dentine of the part affected loses its ivory-white appearance, and becomes transparent and corneous.

Upon a section being made of den-

tine so acted upon, it will be found, both to the naked eye and beneath the lens of few diameters' increase, that these opaque lines are white, and that it is to the size and number of these that the more or less whiteness of ivory in different animals is due.

XII. Perceiving that these lines are capable of being removed or obliterated without any apparent action upon the intertubular structure, I obtained, through the kind assistance of Mr. Napier of Glasgow, a chemical analysis of the diseased and healthy parts, in order to obtain the relative proportion of calcareous salts they might contain when compared with each other. Making use of his experiments, as well as the table given by Mr. Nasmyth upon the authorities of Professor Thomson of Glasgow, and his nephew Dr. Thomson, I find that there is a deficiency of carbonate of lime in the dentine from which the fibres or tubes are absent, when compared with that found in normal ivory.

Taking the average of perfect dentine to contain 7 per cent. of carbonate of lime, that of the diseased or corneous dentine appears to be about 5.25 per cent.; and I think, if we could obtain good samples, and moreover remove the cementum, the proportion would be still less.

I do not mean to put forth these experiments as conclusive, since the quantity of carbonate of lime in dentine is variable. In some experiments the result has been as high as 8.23 per cent., and again as low as 2.86. But I believe that this has been owing to indiscriminately taking teeth of all ages, and which have been more or less attacked by the disease above described.

XIII. Upon testing these observations by comparative anatomy, it will be found that in the hippopotamus, the whitest of all ivory, the opaque lines are most numerous, and the carbonate of lime very abundant, as much as 9.14 per cent. So, also, does the white or external portion of the walrus contain more carbonate of lime than the internal, in the proportion of 4.38 to 1.08; and it appears to hold good as a rule, that white ivory contains more carbonate of lime than the more transparent or green ivory; or, in other words, that the whiteness of ivory is dependent upon the quantity of carbonate of lime which it contains.

XIV. Viewing these facts in connection, I think there is a legitimate basis wherewith to argue that these opaque lines are due to the presence of carbonate of lime; that they are tubes in the earlier part of their formation, but they ultimately become filled, more or less, with the calcareous salt; and upon their filling up depends the perfection of the dentine.

XV. Long after I had arrived at this conclusion, I found the idea had already been suggested to the observant mind of Mr. Tomes, but who has since found reasons to abandon it. Believing, however, that his experiment assists to prove the fact, I shall quote his own words:—

“In the year 1837 I was engaged in examining the structure of teeth, and then came to the conclusion that the dentinal tubes contained an amorphous salt of lime. My opinion was grounded on the following experiment:—After preparing a thin section of human tooth, I placed it in the field of the microscope, and then added a little muriatic acid. No sooner was the acid in contact with the section than evidence of chemical action was rendered visible by the appearance of bubbles of gas, and these emanated not only from the external surface of the section, but also from the interior of the tubes, from which bubbles of gas were seen issuing in quick succession. When the action ceased, the tubes no longer presented the appearance of opaque dark lines, but were indistinctly seen filled with transparent fluid.

At the time, much struck with the result of the experiment, I was led to the opinion that the gas generated in the tubes was produced by the decomposition of their solid contents, which I supposed to be carbonate of lime. However, upon more extended observations, I was induced, from examination of teeth in which the tubes are large, and also from the examination of tubuli of the human tooth with a high power, to modify my first opinion, and was compelled to adopt the views advanced in the former part of the lecture, and to regard the evolution of gas from the tubuli as evidence of the facility with which fluids are admitted into their interior, and to consider that the source of the gas existed in the decomposition of the parietes of the tubes rather than their contents.”

The idea is also approximated by

Prof. Owen, who states, in his *Odontography*, that the tubes ultimately become filled with a granulous material.

And it may be inferred, from the following sentence, that a similar opinion was held by Retzius, who says, “The calcareous salts of the tooth exist not merely in the tubuli, but also in the intermediate substance, which contains, at all events, the greater part of the calcareous earth, either chemically united with cartilage, or deposited in it in an invisible manner.”

I have previously shown that, in the early formation of dentine, these tubes are formed by the compression of the blood-vessels of the pulp by the dentine cells. When the blood ceases to penetrate the structure, the membranous walls then ossify with the rest of the structure, and according to the thickness of the membrane would be the more or less perfect filling up of the tubes. In those animals in which the tubuli of the dentine is large, the probability is that they would be less perfectly filled than in others where the tubuli are smaller: hence the cause which led Mr. Tomes to abandon the idea.

To this cause may be attributed the perfection of the hippopotamus ivory; the tubes are more numerous and minute, while the carbonate of lime is more abundant than in other animals; whilst the phosphate of lime is rather less than in some dentine, which is neither so hard nor durable.

XVI. It is, I believe, a fact that carbonate of lime is not formed in the blood. If this be true, then we must presume that this salt, as found in teeth and bones, must be formed during their development.

The super-phosphate of lime, we know, is secreted from the blood by a power (similar, probably, to endosmose) in the cells; but it appears that in the teeth carbonate of lime is only present in combination with membranous tissue, such as the parietes of cells, blood-vessels, areolar tissue, &c. An example of the last may be seen in the following figure, in which the areolar tissue of the pulp is seen to form part of the structure of the dentine* (Fig. 8).

* The tooth from which the section was taken was free from caries, and extracted from the mouth of an individual between 50 and 60 years of age.

Fig. 8.

FIG. 8. Section of human dentine, exhibiting the ossification of the areolar tissue of the pulp with the rest of the tooth: from a specimen kept some months in writing ink.

XVII. Thus carbonate of soda is present as an amorphous salt in combination with animal tissue, and by its presence converts the parietes of the different classes of vessels which make up the pulp into bone, while the cells have the power of secreting the phosphate only.

In corroboration of this idea, I would wish to draw attention to the ossification of distinct centres of dentine in the pulps of teeth. These apparently commence in a single cell; and as such I have often met with them in the pulps of human adult teeth: so, also, in a well-grown calf; but they seem to be more common in the cachalot, if we may judge from the nodular appearance of the internal surface of the teeth of this mammal, which become more or less incorporated with the true dentine as development takes place, and the latter encroaches on the magnitude of the pulp.

It seems that an isolated cell obtains the power of secreting calcareous matter, similar to those in which the action appears to be normal, only when in connection with the periphery of the pulp.

These centres have all the appearance of being single cells, and, being so, are transparent, and in texture resemble the intertubular structure of dentine. These, being once formed, become the nucleus of a deposit of dentine distinct from the dentine of the tooth: but why some cells have the power of secreting calcareous matter, and others that of reproducing more of their own kind, is

yet to be made known. That it is a condition of the cells, and not its position in relation to the pulp, which induces the secretion, is apparent from the fact that these isolated centres do exist.

XVIII. That the dentine of the teeth are developed in a similar manner to bone can only be considered an approximation to the truth, and that not of the nearest: whereas, by a consideration of their origin from the mucous membrane, and the whole manner in which their development is carried on, little can, I think, be observed, except the presence of a calcareous salt, that can separate it from the remainder of the external skin of animals; to which it may be compared, as holding a relation similar to that which the scales of a fish do to the soft skin on which they are attached, of which the bony scales of the sturgeon (*Acipenser Sturio*) affords the most ready example.

XIX. In fact further to substantiate this remark, I would draw attention to the formation of the calcareous dermal skeleton of crustacea.*

No real difference, I think, can be observed between the development of the shell of the crab and that of the teeth in higher animals. They both are developed from a pulp consisting of areolar tissue, blood-vessels, and nucleated cells, which last have the power of reproducing others smaller than themselves, which ultimately combine without any inter-cellular plasma to form a pavement, into which structure calcareous matter is deposited.

But if we confine our observations more immediately to the teeth of this tribe of animals, which are identical, both in composition and manner of development, with the rest of the shell of which they form a part, no difference can be made out between their formation and that of true teeth, except that an arrest of development takes place in the crab with the deposit of the scale or layer of osseous tissue, which arrest continues for a definite period, when development again proceeds.

To this analogy reference will again be made under the head of "Shedding."

[To be continued.]

* Dr. Carpenter, in his manual, has noticed the analogy which exists between dentine and the calcareous shells of crustacea; but his remarks relate to the density of the shell, and bears no reference to its development, which, as

MEDICAL GAZETTE.

FRIDAY, AUGUST 23, 1850.

We have now before us the Bill for the Incorporation of the General Practitioners, as it has been recently laid before Parliament by Mr. Wyld and Colonel Thompson. If we do not reprint it, it is because its clauses have already in substance been fully and widely circulated in the various editions of Sir James Graham's Medical Reform measures. As embodying the views, however, of a respectable portion of the profession, we consider it to be our duty to advert to the principles, and to give an outline of the clauses of the bill.

The new Incorporation is to be designated the Royal College of General Practitioners in Medicine, Surgery, and Midwifery. The College is to consist of an unlimited number of members, and to be governed by a President and Council. The right of membership is to be extended to all practitioners with a single, double, English, Irish, or Scotch qualification, provided it be claimed within one year after the passing of the Act by residents, and within two years by those who are non-resident in the United Kingdom. The order of precedence is to be settled by the date at which membership is claimed, and to be determined by the date of the new diploma issued by the College.

New members will be admitted only after they have attained the age of twenty-two years, and have completed

the course of study, and undergone the examinations, required by the Council of the College. The fee for the diploma is left blank. Graduates of Universities, or members of the Royal College of Physicians in London, will be entitled to admission without examination (*ad eundem*) on the payment of a fee, provided they have attained the age of twenty-two years, and can give proof of having devoted at least five years to professional study. A Registration clause provides that a register of the names of members shall be published yearly in the month of March: and a correct list is ensured by the infliction of penal disqualification on the omission of a member to send his name, place of abode, with change of residence, &c., yearly to the Council.

The Council is to consist of forty-eight members, of whom not fewer than twenty-four must reside within ten miles of the city of London. The President, after the first nomination, to be elected by the Council and to hold office for three years. The election of Members of Council is to be placed in the hands of members of *five years'* standing, or whose diplomas (from other Colleges) shall show that they have been five years in the profession. The qualification of President or Member of the Council is to be fifteen years' membership, or fifteen years' possession of any diploma, by virtue of which he may have become a member of the College.

The powers of the Council will be much the same as in other Colleges: there will be an annual general meeting for considering and reviewing the bye-laws made for the government of the College, &c.—the bye-laws to have no legal force until sanctioned and approved by the Secretary of State. The 24th clause provides for the registration of students on the payment of a fee of half-a-crown by each student. The examiners are to be annually appointed by

far as I am aware, has never previously been observed to originate in a pulp. The only place that I am conscious of its development being at all referred to, is in Dr. Carpenter's Principles of Physiology, wherein he mentions having seen the new shell of a crab soon after the exuvia had been cast, and imagines that it must have had its origin in cells.

the Council, and no President or Member of Council shall be eligible; but the President, one of the Vice-presidents, or some member of Council appointed for the purpose, shall be present and shall preside at, but not interfere with the examination.

Another clause provides for the expulsion of members guilty of misconduct.

The 27th clause supersedes the existing rights of licentiates of the Apothecaries' Society, and of the members or licentiates of all other Colleges or Universities in the kingdom, excepting those of members of the Royal Colleges of Physicians and Surgeons of England. Thus all appointments to Hospitals, Prisons, Infirmaries, or other public institutions in the United Kingdom, are reserved to those who are registered under this Act, with the two exceptions above mentioned. The exemption from serving on juries is also similarly reserved to registered surgeon-apothecaries or general practitioners. Perhaps we have not clearly understood this clause, but, as we take it, a member of the Royal College of Surgeons of Edinburgh or Dublin would not be entitled to take the office of surgeon to any Hospital or Infirmary in the United Kingdom, unless he had previously enrolled himself as a general practitioner in the new College, or had procured the diploma of the Royal College of Surgeons of England. Again, as we understand it, the power of granting medical certificates in any case required by law is limited to members of the Colleges of Physicians and Surgeons of England, and of the new College of Surgeon-apothecaries or General Practitioners.

We may here just inquire whether the Irish and Scotch Colleges have consented to this act of self-immolation for the benefit of English surgeon-apothecaries, or whether there has been

an oversight in the construction of the clause.

The power of recovering charges for medical and surgical advice and attendance, and for medicines prescribed or administered to patients, is reserved to the enrolled members of the new College, and to those who legally enjoyed this privilege before its foundation.

The 29th Clause is not very intelligible. It proposes to impose a penalty of twenty pounds on *unqualified* persons, but it substantially inflicts this penalty on *every surgeon and apothecary, or general practitioner, not qualified according to the provisions of the act*, who shall unlawfully or knowingly practise in any medical or surgical office to which *he has been appointed*. The summary process of the County Court is for this purpose placed at the option of the prosecutor.

We must here pause to inquire whether this *persecution* of surgeon-apothecaries or general practitioners can be seriously intended by the framers of the bill: A man licensed by the College of Surgeons and the Society of Apothecaries may entertain a distrust of the new College, and decline to surrender his connection with old institutions for the membership of a new and untried foundation. This clause, it appears to us, would render him liable to a penalty of twenty pounds, recoverable in a County Court, if, without having qualified himself according to the provisions of the act, he practised in any medical or surgical office. There is no penalty under this clause on any person *not* being a surgeon-apothecary or general practitioner, for knowingly acting or practising in such office.

Admitting that, by the 27th clause, a Member of the College of Surgeons of England might possibly claim exemption from the penalty inflicted by the 29th, the latter exposes to the tricks of all informers, men qualified

and licensed to practise by the English Society of Apothecaries and by the Scotch and Irish Colleges; while it shields from prosecution those who have the good luck not to belong to any College whatever, and who have received no medical or surgical education! The 27th clause should therefore be entitled, —one for imposing a penalty on *qualified persons* who have neglected or have deliberately refused to join the new College.*

The 30th clause imposes a penalty of twenty pounds upon all persons who practise as surgeon-apothecaries or general practitioners in England and Wales, but who are not registered under the act.

Lastly, a "General Practitioner" is defined under the act to be any qualified person "practising the science and practice of medicine as an apothecary, or the art and science of surgery, and the science or practice of medicine, conjointly, with or without the art or science of midwifery." Hence it comprises all licensed physicians, surgeons, and apothecaries.

Such, then, is an outline of the proposed new act on Medical Reform. It abolishes the Society of Apothecaries, and it practically annihilates the rights and privileges of all the medical corporations in the United Kingdom, excepting those of the Royal Colleges of Physicians and Surgeons of England.

We believe that it will not meet with a favourable reception in any one of the three kingdoms. The English Colleges of Physicians and Surgeons will resist the licensing by examination in medi-

cine and surgery, the effect of which would be in the end to deprive them of their present position by withdrawing candidates for their diplomas. The reserving of the rights of members in case, would be no compensation for withdrawing members in *posse*: and it is a fair question whether by such a change the public would not be serious losers in the *surgical* department of the profession.

The Scotch and Irish Colleges would be even more damaged by the provisions of this bill. Their members would be compelled to enrol themselves as general practitioners, or to forego the rights and privileges which they now enjoy—if not by law, at least by custom.

Setting aside the opposition which such a bill is likely to encounter from all the medical corporations of the empire, its provisions will not, we believe, be found in accordance with the wishes of the majority of the profession in any one of the three kingdoms. There is therefore not the slightest prospect of its becoming law. The profession desire, not a new College reaching only the level of the Society of Apothecaries, and falling far below that of the Royal College of Surgeons, but a modification of the laws by which our medical corporations are at present governed, and a reduction in the number of licensing bodies.

The great obstacle to the settlement of the question of Medical Reform is, that it is difficult to find even ten practitioners who agree to the amount and nature of the modification which the laws and regulations of our Colleges should undergo. The present bill does not remove this obstacle. There is a restricted suffrage, with a triennial presidentship and membership of council. The Council are too numerous for a practical working body: the *senior* would soon take the lead of the *extra-urbs* members; and their proceedings regard-

* The looseness with which this clause is drawn up, reminds us of one in an intended penal act for altering parish registers. A clause specified that *one-half* of the penalty should go to the informer, and the other half to the Queen: another clause described the said penalty to be "seven years' transportation." The blunder was fortunately discovered before the measure became law, or Her Majesty would have only escaped three and a half years' transportation by a dearth of informers.

ing fees, examinations, the disposition of funds, and the restriction of privileges, would, if conceded, give rise within six months to as great dissatisfaction as now exists with respect to older and tried institutions. For all these reasons, we believe that the Secretary of State will pause before he adopts this bill as a remedy for the grievances of which the profession complains.

In the extract of a letter published in the leading article of our last number,* Dr. Letheby states that it was admitted by Sir Benjamin Brodie and others, that the questions put to him by the judge placed him in a very unsatisfactory and unenviable position. In a note at the conclusion of the leading article, we expressed our surprise that such an admission should have been made, because obviously it is not a question, but the answer, which is liable to place a witness in an unsatisfactory position. We have heard from an authentic source, that such an admission as that imputed to him by Dr. Letheby was not made by Sir Benjamin Brodie.

INTERCOSTAL NEURALGIA IN PHTHISIS.

M. BEAU relates some cases whence he deduces the conclusion that a neuralgic intercostal pain is one of the earliest indications of phthisis. The seat of pain is usually in the sixth or seventh intercostal nerve, and most frequently on the left side. M. Beau also states that a neuralgic pain between the shoulders may be regarded as almost constantly a premonitory symptom of phthisis, and that this results from the dyspepsia which precedes the deposition of tubercle.—*L'Union Médicale*. X

ARREST OF HEMORRHAGE BY MATICO.

THE stump of an arm, amputated near the shoulder, bled secondarily to a dangerous amount, from the whole surface. Pressure having failed, a paste was made by moistening powdered matico, and this was spread over the part. It acted as an artificial coagulum, and checked the flow of blood, which did not afterwards return. The only other remedy would have been to tie the subclavian artery.—*Dr. Hartshorne, in American Journal of Med. Sciences, Jan.*

Reviews.

A Practical Treatise on Diseases affecting the Skin. By the late ANTHONY TODD THOMSON, M.D., F.L.S., &c. &c. Completed and edited by EDMUND A. PARKES, M.D. 8vo. pp. 440. London: Longman and Co. 1850.

WE are informed by the editor's preface that for more than a year previous to his last fatal illness, Dr. Thomson was engaged in the preparation of a Treatise on Diseases affecting the Skin. About three hundred pages only of this work were printed, the articles Acne and Syccosis also being left in MS. Dr. Parkes has undertaken the task of completing the work. No fitter or more competent person could have been found for the purpose. Dr. Parkes is nephew to the late Dr. Thomson, was several years his assistant in his museum and laboratory at University College, received his private instructions when a student of medicine, has since highly distinguished himself by his professional acquirements, and, lastly, has become intimately familiar with Dr. Thomson's views on the subject of the present work, by his close association with him in the daily labours of his latter years. We can therefore confidently assure our readers that Dr. Parkes's additions will faithfully convey the spirit of Dr. Thomson's pathological and therapeutic opinions and practice.

The work itself is preceded by a Memoir of Dr. Thomson, in which, although anonymous, we think we can trace the pen, and the affections, of the accomplished authoress of "The Life of Sarah, Duchess of Marlborough."

In order to present our readers with a general view of the contents of a work the nature of which almost forbids quotations, we shall in the first place adduce the author's arrangement.

1. Febrile contagious diseases non-recurrent, except in exceptional cases, —including the exanthemata.
2. Febrile contagious diseases capable of recurrence many times during life, —including the varieties of erysipelas.
3. Non-febrile contagious diseases—porrigo, scabies, &c.
4. Non-contagious febrile diseases—erythema, urticaria, &c.
5. Non-contagious, non-febrile dis-

eases, chiefly connected with, and characteristic of, derangements of the digestive, assimilating, and secreting organs. This is divided into six orders of eruptions—papular, pustular, vesicular, squamous, tuberiform or tubercular, and hæmorrhage.

6. Diseases not included in the former division, or of doubtful position.

7. Syphilides.

8. Non-eruptive morbid states of the skin,—including hypertrophies of its tissues, pigmentary alterations, abnormal conditions of the glands, acne, sycosis, abnormal conditions of the hair-follicles and hair.

9. New formations of the skin.

10. Diseases of the nails.

An appendix by the editor contains the results of the most recent investigations into the minute anatomy of several forms of cutaneous disease.

Dr. Parkes's remarks with reference to the classification of *porrigo favosa*, *lupinosa*, and *scutulata*, certainly exhibit the almost insuperable difficulties which attend any general arrangement of skin-diseases,—a difficulty obviously felt by Dr. Thomson, and not removed by the classification adopted in the work before us. We believe that the natural arrangement proposed by Erasmus Wilson will be found to form ultimately the best for practical purposes. The classification of skin-diseases according to their contagiousness or non-contagiousness is peculiarly open to objection. Thus, *erysipelas* forms a class by itself in Dr. Thomson's arrangement, on account of its contagious character; but it is well known that this is a property which this disease does not invariably possess, and which, when manifested, is superinduced by certain unfavourable concomitant conditions; such as the impure air of imperfectly ventilated apartments, neglect of cleanliness, peculiar epidemic constitutions of seasons, &c.

Our readers will perhaps be surprised to find doubts expressed on the influence of the *acarus scabiei* in the causation of itch. Dr. Thomson observes—

"That the disease is contagious there is no doubt; and, in my opinion, it is equally certain that it is the result of a morbid poison; and that the fluid of the vesicles or the pustules is the agent transmitting the disease from one person to another. This opinion, however, is strongly opposed in the present day. Among other opinions, Abinzoar, in the 12th century, sug-

gested the idea that the disease originated from an insect which he first described. His opinion was revived by Gabucinus, Ingrassias, Laurence, Joubert, and some other writers of the 15th and 16th centuries, all of whom saw and described the insect, which they regarded as an *Acarus*. A fact adverse to this opinion, however, was pointed out by Moutet, who found that the insect did not reside in the vesicles or pustules, but only near them; an observation that has been subsequently confirmed. There is now no doubt of the existence of the insect; it was examined under the microscope, and figured, first by Hauptmann in 1654, then by Bonomo in 1683. But, although the existence of the insect cannot be doubted, yet there are many reasons for not regarding it as the origin of the disease; although the disease may be transmitted by the conveyance of the poison necessarily attached to the insect when it passes from one person to another. I would refer those who are desirous of tracing the discovery, the nature, and the habits of this animalcule, to a most excellent monograph on the subject, at the end of Mr. Erasmus Wilson's *Treatise on Diseases of the Skin*. But awarding to Mr. Wilson the merit which he justly deserves, . . . I cannot accord with him in attributing the disease to that insect. Were scabies of insect origin, we must suppose that the ova floating in the atmosphere would be deposited and find their nidus, and the insects generated from them their proper food, in numberless individuals: hence we should have daily and numerous instances of spontaneous scabies, which, if it ever occurs, is very rare."

Impetigo, the author observes, is often mistaken for scabies. That the insect has a closer relationship with the disease than is here admitted by Dr. Thomson, we consider the whole history of the animalcule to testify. Granting that the entry of the insect into the skin of one individual may convey the fluid from the body of another, and so be the means of performing the veritable inoculation for which Dr. Thomson contends; yet this only more strongly confirms the view of its being the cause of the disease; and reasoning by way of exclusion, in what other relation has the author shown the insect to stand to the disease? The existence of the insect is admitted; its residence also in the itch-vesicle is admitted, or it could not be the medium of the transmission of the morbid fluid; it is not found elsewhere;—it must

therefore either be a cause or a consequence; how the latter, we can in no way imagine, except by supposing the presence of ova on everybody's skin, ready to be developed into acari when the right sort of eruption shall occur.

Dr. Thomson's observations on the symptoms and diagnosis of cutaneous diseases are comprehensive yet precise: these are in every case followed by the consideration of the cause of each disease, and this in turn is succeeded by the study of its prognosis and treatment. In discussing the latter, the author's long pursuit of the study of *materia medica* and therapeutics furnishes him with an abundance of means of treatment. We cannot, however, concur in the frequency or extent to which the author advocates depletion, both local and general.

Among Dr. Parkes's contributions to this volume, we may observe that the chapters on Elephantiasis, and on Syphilitic Eruptions, are peculiarly exact. In point of strictness, the latter should not have been disjointed from analogous forms of disease noticed in previous classes: a notice of their special characters under the head of cause, in some previous order, would have done less violence to the author's arrangement. In like manner we can see no reason why Acne and Sycoosis should not have found places in one or other of the preceding classes or orders.

The inconveniences, however, which would otherwise have been experienced from a faulty classification, are very much obviated by the copious index which the editor has furnished. In the performance of his editorial duties, Dr. Parkes has faithfully represented the author's views, and used his utmost efforts to render the work acceptable to the profession. We entertain no doubt that many will find this work a useful assistant in a class of cases most tedious in their course, and difficult of management: they will, as we have already observed, find in it copious and valuable details in diagnosis and therapeutics.

The Principles of Surgery. By JOHN A. ORR, A.B., F.R.C.S.I., one of the Surgeons of the City of Dublin Hospital. Small 8vo. pp. 496. Dublin: Fannin. London: Churchill. 1850.

THIS volume, which is published in the style of Churchill's *Manuals*, is intended

to set before the student, in a condensed form, the present state of surgical science. The following extract from the preface will afford some indication of the nature and extent of the author's intentions in its publication:—

"To make a strictly scientific classification of the various subjects that require notice in a treatise on surgery, would perhaps be impossible. The arrangement which I have adopted is at least simple. In the first part, the theory and management of the inflammatory process are detailed; in the second, the various kinds of injuries, commencing with wounds and their consequences; then fractures and luxations, burns, and scalds; and, lastly, contusions, which I have placed in that position from having adopted Velpeau's classification of those injuries. The third part includes the diseases commonly called surgical, beginning with those which affect the constitution at large, and proceeding to those which affect particular systems and organs.

"To the conclusion of each chapter I have appended the names of some of the principal authors who have written on the subject described; and, in enumerating different modes of treatment, I have generally added the name, either of the inventor, or of the most distinguished authority who has adopted it. In many cases I have introduced considerable quotations from the best authorities, which may occasionally appear rather abrupt; but I preferred giving the *ipsissima verba*, even with this disadvantage, to remodelling the language of another writer."

Having looked through this treatise, we can speak favourably of it as a compendium of the most recent information on the science of surgery, and on the treatment of surgical diseases and accidents.

The Causes, Symptoms, and Treatment of Eccentric Nervous Affections. By WILLIAM JOHN ANDERSON, F.R.C.S. 12mo. pp. 199. London: Churchill. 1850.

THIS work is composed of a series of cases selected for the most part from the practice of Dr. Seymour at St. George's Hospital, with observations or commentary thereon; and is dedicated to the same physician as a "grateful acknowledgment of the kind and valuable instruction received from him by his former pupil, the author." It consists of six chapters, which treat of—

1. The intimate connection between the nervous and circulating systems; a general description of the phenomena of the circulation, and of assimilation, and of the nervous system. 2. The difference between centric and eccentric nervous affections; with illustrative cases. 3. Hysteria and hypochondriasis; their causes, treatment, &c. 4. Epilepsy. 5. Collapse, from shock, delirium traumaticum, and tetanus. 6. Delirium tremens and hydrophobia.

We commenced the perusal of this book with the hope, from its title and the promises of its preface, of learning something which we did not before know on the subjects on which it professes to treat; but we have been disappointed therein. We are, indeed, entirely at a loss to discover the object of the publication of a work so devoid of originality, otherwise than as a literary exercitation for the author's own benefit, and the opportunity it affords for a dedication.

Disease of the Urinary Organs.

M. CIVIALE read a report on a case of chronic inflammation of the bladder which had been transmitted by M. Mordret, surgeon of the Military Hospital of the Isle of Oleron.

The patient was thirty-eight years of age, had suffered from infancy with difficulty in micturition. Complete retention proved fatal. After death the bladder was found to be hypertrophied, multilocular, and the seat of extensive inflammatory disease.

M. JOBERT DE LAMBALLE reported on two cases of the operation for stone transmitted by Dr. Cazenave, of Bourdeaux, in which, on account of the size of the calculi in the one case, and of the presence of a tumor in the other, it was necessary to have recourse to numerous unusual incisions.

Preparation of Pills of Iodide of Iron.

M. LECANU read a report on the means proposed by M.M. Gille and Blanchard to protect iodide of iron, in the form of pills, from the action of the oxygen of the air,

and which consisted in varnishing the pills with a solution of balsam of tolu in ether.

SURGICAL SOCIETY OF PARIS.

August 7, 1850.

Amputation of both Superior Maxillary Bones.

M. MAISONNEUVE had performed this operation on a man, aged sixty-nine years, suffering under cancer of the bones. The same operation had been successfully performed on a young girl affected with necrosis from the vapour of phosphorus. M. Maisonneuve detailed the steps of the operation, and its result, in the first case. A vertical incision was made in the middle line, dividing the nose from its root, and terminating at the upper lip; a transverse incision was then made from the internal angle of the right to that of the left eye; two large quadrilateral flaps were thus left to be dissected down, following the edge of the eyelid to the external angle on both sides: when these were everted the disease was fully exposed. A chain saw was passed through the spheno-maxillary fissure; another was passed through the root of the nose, traversing the os unguis on both sides. In this manner the bones were detached laterally and superiorly. Posteriorly, the velum palati, which was healthy, was detached with a bistoury: then, by the help of Liston's forceps, the entire mass of the bones was detached. The result of the operation at first promised favourably, but in a few days the patient died.

Disease of the Bones of the Hand.

M. CHASSAIGNAC presented a case of disease of the bones of the hand, the nature of which was somewhat obscure, and in which, as symptoms of tubercular disease of the lungs were also present, it became a question whether amputation should be had recourse to. After some discussion, it was deemed advisable to administer internal remedies, and to postpone the operation for the present.

ACADEMY OF SCIENCES, PARIS.

August 12, 1850.

Physiology of the Heart.

M. FATON transmitted an essay containing his researches on the sounds and movements of the heart. The following are among the chief conclusions at which the author had arrived:—

The entire volume of the vascular system

of the thorax undergoes no sensible change from the play of the different parts of the heart whilst that organ performs one complete beat; the heart itself undergoes but little change of form or situation by the contraction of its different parts. The changes in the capacity of the auricles and ventricles result principally from the displacement of the auriculo-ventricular septum, which is more extensively displaced than either of the walls of the heart during its movements. The dilatation of the cavities results from the antagonism of the fibres on each side of this septum, from the tendency to contraction in the lungs, and from the afflux of blood into the cavities of the heart. The base only of the ventricles is displaced during their systole. The heart exerts the action of suction on the veins, by which it influences the circulation in these and the lymphatics. The heart and thoracic vessels are augmented slightly in size during inspiration, and diminished during expiration: the respiratory movements contribute to the force and rapidity of the circulation of the blood. The rapidity of the circulation is not in relation to the frequency of the pulse. The venous blood continues to flow into the heart during the contraction of the auricles. Expiration produces no reflux in the retrograde course of the circulation.

Vesico-uterine and Utero-vesico-vaginal Fistula.

M. JOBERT DE LAMBALLE submitted a memoir, in which he stated, as the result of his researches into the nature and treatment of these accidents, that the injuries thereby incurred, and which have been hitherto regarded as incurable, are no less curable than vesico-vaginal fistulae, by the same means as employed for the latter, by himself.

Presence of Urea in the Liquor Amnii.

M. BALARD stated, in the name of M. Regnaud, that the latter chemist had, by the qualitative analysis of some carefully procured liquor amnii, obtained pure crystallized urea from that fluid.

Cholera.

M. VILFRAU presented a memoir by Dr. Pellarin which proved the contagiousness of cholera, from facts attending its importation into Finisterre from Brast. The author cited numerous other examples of the spread of the disease in hospitals concurrently with the reception of cholera patients where it had not before appeared.

Correspondence.

ON THE INFLUENCE OF FOOD IN THE DEVELOPMENT OF OXALATE OF LIME IN THE SYSTEM. BY C. B. ROSE, ESQ. F.R.C.S. [COMMUNICATED BY DR. GOLDING BIRD.]

To Dr. Golding Bird, F.R.S.

MY DEAR SIR,—The perusal of your valuable work on "Urinary Deposits," resuscitated my early taste for similar inquiries, and has led me to watch, with renewed industry, the changes that are constantly taking place in the secretion from the kidney, both in health and disease. Your "discovery of the comparative frequency of oxalate of lime in the urine in fine and well-defined octohedral crystals, and of the connection between the occurrence of this substance and the existence of certain definite ailments, all characterised by great nervous irritability,"* has induced me to pay attention more particularly to that form of abnormal secretion.

After examining what has been written by yourself and others on the deposit of oxalate of lime in the urine, since your observations first appeared, it has occurred to me that it would be a useful inquiry to ascertain how far the elimination of oxalate of lime by the kidney was the effect and a pathognomonic sign of a *certain definite ailment*, or how frequently it was the consequence of a form of dyspepsia merely, or in what degree it was dependent upon the ingestion of certain articles of diet; and I have therefore, for some length of time, undertaken and pursued this inquiry, but more especially with reference to the last point.

I have been in some degree led to question the opinion that a connection *invariably* obtained between the occurrence of oxalate of lime in the urine and the "existence of certain definite ailments," by a case that I will relate, in which the oxalate of lime continued to be eliminated by the kidneys for months after the patient was, to all appearance, in perfect health; and, further, from having ascertained that certain vegetables and fruits in daily dietetic use were capable of inducing or of leading to the production of a like deposit.†

* Urinary Deposits, 1st edit., p. 123.

† Since writing the above, I have met with the following observation of that profound philosopher, Dr. W. H. Wollaston, which makes manifest how greatly he was in advance of the chemistry of his time, as applicable to pathology and therapeutics. "With respect to the mulberry calculus, I fear that an intimate knowledge of its properties will leave but small prospect of relief from any solvent; but, by tracing the source of

CASE.—On July 25th, 1849, I was requested to see a lad, eleven years of age, who had been ill some weeks, with symptoms of dyspepsia: I found him looking sallow, so much so, indeed, that I at the moment thought he must be labouring under an attack of jaundice. His parents said that he had wasted considerably. All that I could learn respecting his state of health during the period of his indisposition was, that several months previously he was attacked with diarrhoea, and that he had been in a state of *malaise* ever since. At the present time his appearance was dull; his complexion was very peculiar; his skin looked dirty; indeed, his mother had repeatedly told him that he did not wash his face; his tongue was covered with a dirty-coloured fur; his abdomen was tumid, but his bowels were tolerably regular, and his faeces were quite of a healthy character; his urine possessed a dark amber colour, exhibited a slight mucous cloud, gave a considerable deposit of uric acid crystals, with a slight excess of urea; sp. gr. 1027. On examining it in the usual way for oxalate of lime, I met with an abundance of its crystals. I prescribed for him a saline diuretic mixture; an alternative, with a diaphoretic, at bed-time.

July 28.—My notes inform me that the lad looks briske in the face, and with a less dirty complexion: he passes nearly two pints of urine in the twenty-four hours, of not so dark an amber colour; sp. gr. 1025; has a large deposit of uric acid, as red sand; gives a considerable excess of urea, and shows an abundant crop of crystals of oxalate of lime; the urine also exhibits a highly acid reaction with litmus.—Prescribed five minims of Tincture of Sesquichloride of Iron, in Infusion of Quassia, three times a day.

August 2nd.—The patient is looking better; his complexion is less sallow, and he is more lively; his appetite is good; his body not now tumid; his bowels are regular, but his tongue continues furred; urine not so highly amber-coloured; sp. gr. 1027; abundance of uric acid crystals; urea in excess, but not quite so much oxalate of lime; a few large crystals were exhibited.—Ordered five minims of the Wine of Colchicum to each dose of the Chalybeate.

5th.—The lad appears more cheerful, and eats well; he never touches

the disease, we may entertain some hopes of preventing it. As the saccharine acid is known to be a natural product of a species of oxalis, it seems more probable that it is contained in some other vegetables, or their fruits, taken as aliments, than produced by the digestive powers, or secreted by any diseased action of the kidneys. The nutriment would therefore become a subject of minute inquiry, rather than any supposed defect of assimilation or secretion.—See Philomoph. Trans. (abridged), vol. xviii. p. 220, 1797.

cooked vegetables or fruits; he still retains a considerable degree of sallowness; his urine has the same amount of uric acid sediment, and excess of urea; oxalate of lime quite as abundant; dumb-bell crystals exhibited with the octohedral.—He is to continue taking the colchicum and chalybeate.

12th.—The lad's complexion is much better, and his health is altogether improved: urine paler, with less deposit of uric acid; sp. gr. 1030; much less oxalate of lime visible, and no excess of urea.—Discontinued my regular attendance.

October 25th.—I called on the lad, who says he is quite well: he eats, drinks, and sleeps well, and appears to have regained his usual spirits, as when in health; his complexion is clear. I procured some of his urine, and found it of a pale sherry colour, with a slight mucous sediment, and deposits but little uric acid; sp. gr. 1020. There is at this time a great abundance of oxalate of lime in both octohedral and dumb-bell crystals. He is taking no medicine.

April 23, 1850.—I examined the urine of the lad, who continues to enjoy good health: his night's and morning's urine amounts to 18 ounces; it is of a pale sherry colour, with slight uric acid sediment; sp. gr. 1025; it contains a considerable excess of urea, and an abundance of oxalate of lime, in minute crystals, without any of the dumb-bell form. This lad's daily diet is bread and butter and tea for breakfast, rarely milk; meat, with pudding or dumpling, for dinner, seldom any beer; bread and butter, with tea, again for supper. He eats occasionally, but not frequently, portions of raw turnip and carrot: he had not eaten either at the time of my last examining his urine, and he never, by any chance, eats cooked vegetables of any kind; he is not a greedy or voracious eater.

The peculiar feature of the above case, as you will observe, is the habitual elimination of oxalate of lime by the kidneys, the individual enjoying, in all other respects, perfect health. Can it then be said that the formation of oxalate of lime in the animal fluids is *invariably* a morbid condition?

A nearly similar immunity from morbid symptoms has been noticed by the late Dr. Prout and others. The former observed "that the peculiar symptoms attending the oxalate of lime diathesis vary exceedingly in degree as well as in kind. Sometimes they are so slight as to pass unnoticed by the patient; or at most are considered as dyspeptic derangements of no great importance"*. Dr. Shearman says "the appetite

* Stomach and Urinary Diseases. 3rd edition, page 62.

is often good, and it is almost impossible to get them (the patients) to acknowledge they have any derangement in their organs of digestion.* Mr. Stallard, also, when describing a case of irritable bladder, in which he detected "*large octohedra of oxalate of lime*" in the urine, says "the general health is exceedingly good; has no dyspepsia, and complains of neither depression of spirits, or any of the symptoms described by Dr. Golding Bird as the usual characteristics of the oxalate of lime diathesis."†

The fact of the continuance of apparent health during the elimination of oxalate of lime by the kidneys, as recognised by the above-named observers, and also brought to my own notice by the case related, has excited me to look for some other cause or source of this unnatural element than mal-assimilation from ill-digested food, through redundant quantity, or irreducible quality, or diminished power in the digestive organs.

Aware that the edible rhubarb invariably led to the appearance of oxalate of lime in the urine of persons partaking of it, without their experiencing any appreciable derangement of the digestive function, I thought it not improbable that other articles of diet, both vegetables and fruits, in common use might be productive of a like effect. I therefore determined on putting this idea to the test, by instituting a series of experiments; and wanting the opportunities which an hospital affords, I practised them upon myself—which circumstance, I considered, would certainly not render them less satisfactory: and I will now briefly recount these experiments to you, as minute detail would be more tedious than useful.

Having first assured myself that the rhubarb quickly and invariably led to the appearance of the crystals of oxalate of lime in my urine, the plan I adopted was to partake of the selected article at dinner, with my usual form of mutton or beef, &c., drinking water only; then, at the expiration of two and a half to three or more hours, before taking tea with sugar, I passed my urine, which was set aside till the following evening, and its lower stratum then examined, by warming, &c., and the use of the microscope, in the manner you have directed.

I made my first essay of *other aliments* on the *leek*;‡ and in November 1848, I ate

at dinner heartily of boiled leeks, and found an abundance of oxalate of lime in my urine, passed about three hours afterwards.

Jan. 10th and 11th, 1849.—I partook of leeks both days, but no trace of the oxalate was found in the urine passed on either of the days.

Feb. 5th. Ate leeks and no sweets; my urine, passed three hours afterwards, contained a great abundance of oxalate of lime, many crystals as large as if I had eaten rhubarb. The urine made immediately before dinner contained none.

*Onions.**—Partook largely of onion-sauce at dinner, and found in the urine passed three hours after, mixed with some made after taking tea, a few small crystals of oxalate of lime.

After eating, on two successive days, at dinner, largely of *Portugal* onions, my urine, passed from three to six hours after on each day, and put together, examined in the usual way, exhibited an abundance of oxalate of lime in both large and small crystals. These experiments were made in the autumn of 1848.

In September of 1849, after eating heartily of *common* onion-sauce with boiled rabbit, on trying my urine I could not find any oxalate of lime.

November.—I ate plentifully of *Portugal* onions boiled; in the urine passed three hours afterwards I found a very few small crystals of the oxalate: in this instance the urine was examined on the evening of the day on which the onions were eaten; there were none in the urine passed just before dinner. On allowing the urine for this experiment to stand for twenty-four hours before examination, it exhibited an abundance of oxalate of lime. The urine made in the morning *subsequent* to eating the onions furnished none of the oxalate.

Knowing an individual who ate almost daily two or three small raw onions, as an antidote to gravel, I procured some of his urine, made on the day he had eaten the onions, but I could not detect any oxalate of lime in it. There was a copious deposit of crystals of uric acid.

Turnips.—November 1848, I ate heartily of boiled turnips with my meat at dinner, and my urine afterwards gave an abundance of oxalate of lime.

February 1849.—Partook in moderation of boiled turnips with boiled beef; the urine passed three hours after gave an abundance of small crystals of the oxalate.

December 1849.—After eating heartily of boiled turnip, I examined my urine at the usual time, but discovered no oxalate of lime. Probably it ought to have stood

* On the Value of Urinary Diagnosis in the Detection and Treatment of Disease: *Provincial Med. and Surg. Journal*, page 529, 1845.

† LONDON MED. GAZ. vol. ii. page 118, 1846.

‡ Allium porrum. Pereira, speaking of the various species of Allium, says "their virtues are analogous to those of the onion and garlic;" and, on the authority of Fourcroy and Vauquelin, he states that the onion contains uncrystallisable sugar: it is, therefore, probable that the leek also contains sugar.

* Mr. John Quékett informs me that he has discovered crystals of oxalate of lime in the onion.

longer before examination. I occasionally tested the urine on the same evening that it was passed.

January 25th, 1850.—Ate heartily of boiled turnip with mutton; my urine afterwards gave an abundance of *large* and *small* crystals of the oxalate, whilst the urine passed just *before* dinner contained a very few *small* crystals only.

Parsnips.—April 1849: ate heartily of boiled parsnips, and no sweets; examined my urine, passed three hours afterwards, and found an abundance of the oxalate of lime.

February 15th, 1850.—Ate three small parsnips at dinner, and my urine afterwards gave a few *large* crystals of the oxalate.

18th.—I experienced symptoms of slight dyspepsia, and slept badly; my urine, passed immediately *before* dinner, exhibited a great abundance of *minute* crystals of the oxalate. I ate rather heartily of boiled parsnips, with boiled mutton; my urine afterwards gave fewer *small* crystals, with several *large* ones.

Carrot.^{*}—August 17th and 18th: I partook of boiled carrots each day at my dinner; on the 19th, in the evening, I examined the urine passed after dinner on the 18th, and found a few *small* crystals, with two *large*ish ones, of the oxalate.

September 18th.—Ate boiled carrots with my dinner, and a few crystals of oxalate of lime appeared in my urine.

February 1850.—Ate two large boiled carrots at dinner: my urine, passed three hours afterwards, gave a few *large*ish crystals of the oxalate; the urine passed immediately *before* dinner exhibited none.

The ingestion of *cauliflower* or *asparagus* has not, with me, given rise to the oxalate of lime in the urine. Of those vegetables, after the eating of which oxalate of lime is eliminated by the kidneys, I am inclined to believe that after rhubarb, leeks, Portugal onions, and turnips, lead to the production of the largest quantity. Parsnips, and then carrots, appear to produce a smaller quantity. It appears to me, also, that a greater number of *large* crystals are met with after those things have been eaten which in the highest degree tend to the production of oxalate of lime.

Apple.†—Apple pudding and tart, with or without sugar, taken at dinner, invariably gave an abundance of oxalate of lime in my urine, there not having been any in that secreted *before* dinner. Once, having eaten at dessert three raw London

pippins, I examined my urine passed from four to six hours afterwards, but found no trace of oxalate of lime. There was a large quantity of urate of ammonia; the specific gravity of the urine 1025.

Red currants.—I ate, three successive days, of currant pudding at my dinner. The fruit was very acid, requiring sugar. My urine, passed before taking tea, gave a great quantity of oxalate of lime. There was no excess of urea.*

Orange.—January 1850: after eating three oranges, my urine, passed before tea, gave an abundance of *large* and *small* crystals of the oxalate: the urine made just *before* dinner exhibited many *small* crystals; but those after taking the oranges were greatly increased in number and magnitude.

February.—I ate four oranges after a plain dinner, and an abundance of *large* crystals of the oxalate were found in my urine made afterwards. There were none in that passed *before* dinner.

Grapes.—March 1850: I ate at two o'clock a dinner of two mutton chops, potatoes, and Stilton cheese, and drank half a pint of table beer; examined my urine, passed at six P.M.: it contained an abundance of oxalate of lime; it was taken from the lower stratum of ten fluid-ounces of urine. At seven o'clock the same evening I ate nearly a pound of Malaga grapes. I examined the lower portion of five fluid-ounces of my urine passed three hours afterwards: it contained about the same proportion of the oxalate as in the first specimen; the only difference between the two was, that there were several *large* crystals in the last. I afterwards examined the lowest stratum of the urine (20 ounces) passed the following morning at eight o'clock: it exhibited a great abundance of *small* crystals of the oxalate, but no *large* ones. I was not aware of being dyspeptic at this time; still, I am certainly subject to slight derangements of the digestive function, and which will probably account for the following state of things:—

On April 4th of the present year, I examined my urine passed *before* dinner: it contained an abundance of oxalate of lime.

I examined the urine passed three and a half hours after my usual plain dinner: there appeared rather more oxalate, and a few *large* crystals.

I examined the urine passed on the following morning, and found in it a *great* abundance of *small* crystals of the oxalate.

I will now give you the results of exami-

* Pereira informs us, on the authority of Wackenroder, that the expressed juice of the carrot contains uncrystallisable sugar, with some starch and malic acid.

† Mr. Quekett has detected crystals of oxalate of lime in the apple.

* My urine usually contains a full proportion of urea, apparently an excess, not absolutely so; for as I commonly take but a small quantity of fluids, my urine is proportionably concentrated.

nations of the urine made after two or three instances of excess in my ingesta:—

May 7th, 1849.—I dined at an inn: partook of salmon, soup, roast beef, and potato, chicken, sweet pudding, boiled custard, and cheese; drank moderately of Bucoallas, sherry, and port; afterwards took coffee. Examined the next morning's urine, and found a great abundance of the oxalate of lime in it.

8th.—Dined to-day at home upon roast mutton, and ate rather largely of boiled cauliflower, but no sweets. My urine passed immediately before tea exhibited no crystals of the oxalate.

24th.—Dined at an inn: ate fish, soup, mutton, green goose, custard, lemon-cream, and cheese; drank Bucoallas and port; afterwards took tea. Examined the urine passed eight hours after dinner, and found a great abundance of crystals of uric acid, but none of the oxalate of lime.

About a week after the last date I dined with a party at my own table; partook of the usual routine of fish, soup, solid meat, and plum pudding; no pastry; and drank in moderation of sherry and port only. The urine of the following morning, sp. gr. 1022, contained my usual proportion of urea, no excess of uric acid, nor any oxalate of lime.

On reference to certain dates in this communication, it will be seen that the oxalate of lime was not always found in the urine made *after* dinner, although it had previously appeared in the secretion of that period under apparently similar circumstances: for instance, January 10th and 11th, 1849, after eating leeks; September 1849, after onions; and December 1849, on eating turnip. Might not the oxalate have been met with in the urine of the following morning, had it been examined? Dr. Shearman, in a paper from which I have before quoted, makes the following remark:—"It is commonly found that the oxalates are more plentiful in the urine after dinner, or in the urine chylif, than in the morning, or urine sanguinis; and, as the cause of the deposit is supposed to depend on mal-assimilation of the food in the stomach, this seems to be the most likely time to find it. But here (Case 1st) the deposit of oxalate of lime was never found in the urine after any meal, but was always most plentiful in the urine voided in the morning."*

Herein I have laid before you all the data I possess upon this subject, acquired from the experiments my leisure has enabled me to make: they are faithfully recorded, however imperfectly they may

have been prosecuted. I forbear to comment or reason upon them, being conscious of my incapacity for so doing, from my want of a sufficiently intimate knowledge of the metamorphoses and mutations constantly taking place in the proximate elements of the secretion of those scavengers of the animal body—the kidneys.

It will afford me much gratification, and amply repay me for the trouble I have taken, should the results of the above inquiry prove of any practical utility; and I cannot but think that their application in the treatment of cases of oxaluria will at least remind us of the importance of not being satisfied with a *general* direction, but prompt us to prescribe a *special* form of diet, as a necessary adjuvant to our therapeutics.

I am, my dear sir,

Very faithfully yours,

C. B. ROSE, F.R.C.S. &c.

Swaffham, June 27th, 1850.

EVIDENCE ON INTRAMURAL INTERMENTS. UNJUST ATTACK ON THE MEDICAL PROFESSION.

SIR,—Permit me to call your attention, and that of your readers, to the following unwarrantable statements, which I find in the evidence taken by the Board of Health on the Intramural Interment question.

A Mr. Sadler, an undertaker, states, that "it is known that surgeons take commissions" (on funerals); that "one of the evils of the present system is the taking of commissions"—reiterating the charge; "there are medical men who take commissions."

If words mean anything, these words distinctly imply that the taking commissions from undertakers is common among London medical men. The utter want of truth in such a charge, as applied to the profession generally, it is scarcely necessary to point out; but it will be made clearly apparent to any one who will take the trouble of inquiring among his professional brethren, as I have (somewhat superfluously) done. There will not be found an exception to the rule that every one will give an indignant denial to such a charge.

In all my life I had never before heard of such a thing; I therefore took the trouble to inquire of an undertaker, carrying on at this present time a very large business, and he assured me that neither he himself, nor any member of his trade with whom he had spoken on the subject, were aware of any such transactions until they met with Mr. Sadler's assertions; adding, at the same time, that no respectable

* Cases of Oxaluria, by Dr. E. J. Shearman: LONDON MEDICAL GAZETTE, New Series, vol. ii. page 408, 1846.

tradesman would venture so to insult a professional man.

So much for this assertion, that the taking of commissions by surgeons is "*known*." Even if Mr. Sadler has found some "surgeons" with so low an estimate of professional honour as to submit to such a degradation at his hands, still these exceptional instances afford no ground for affixing this stigma of disgrace upon the entire class; such transactions having been *unknown* and secret compacts. If Mr. Sadler had thought the proceeding honourable or professional, he would have given the names of those surgeons who have so lowered themselves and their profession.

Unless this disgraceful charge be substantiated by the proof alluded to—the publication of the names of the commission-takers—it may be fairly assumed that the whole statement is a mere unadulterated fiction, invented to remove censure from the real authors of exorbitant funeral expenses.

I should not have intruded upon your space by noticing so evidently false and calumnious a charge, had it not been dragged from its merited obscurity in the pages of a *blue book*, by a professional publication, the *Edinburgh Monthly Journal of Medical Science*, in which the London surgeons are represented as finding in this way a *solatium* for the results of unsuccessful operations! As a matter of course, I should expect to find this passage copied into the *variétés* of the continental journals. It is therefore needful to give it thus publicly an unqualified and direct denial.—I remain, sir,

Your obedient servant,

W. B. KESTVEN.

Upper Holloway, Aug. 12, 1850.

INFLUENCE OF VACCINATION ON AN EPI-
DEMIC OF SMALL-POX. BY DR. LOMBARD.

IN the department of L'Ariège, where small-pox has been prevalent for several years, and recently with much severity, a hundred and twenty vaccinations were practised in a period of six weeks. Of this number of infants not one was attacked with small-pox, while others died. Even where small-pox was developed to a certain extent, vaccination exerted a favourable influence. M. Lombard states that in those persons in whom variola appeared, and who had been vaccinated some time previously, the severity of the disease increased with the length of that interval. M. Lombard concludes in favour of re-vaccination.

—*Gazette Médicale*.

Medical Intelligence.

HONOURS CONFERRED ON MEDICAL MEN IN
THE ARMY AND NAVY.

THE Queen has been graciously pleased to make and ordain a Special Statute of the Most Hon. Order of the Bath for the purpose of authorizing the admission into the Military Divisions of the second and third classes of the said Most Hon. Order, of such Officers of the Commissariat and Medical Departments of the Army and Navy, and of the East India Company's Army and Navy, as by their meritorious services have already or may hereafter be deemed by Her Majesty to have deserved such distinction. Her Majesty has accordingly been pleased to give orders for appointing—

Sir James M'Grigor, Bart., Doctor of Medicine, Director-General of the Medical Department of the Army;

Sir William Burnett, Knight, Doctor of Medicine, Director-General of the Medical Department of the Navy; and

James Thomson, Esq., Inspector-General of Hospitals on the Bengal Establishment of the East India Company's Service, to be Ordinary Members of the Military Division of the Second Class, or *Knight Commanders* of the said Order.

And Her Majesty has further been pleased to give orders for appointing the following Officers to be Ordinary Members of the Military Division of the Third Class, or *Companions of the said Most Hon. Order*, viz.:

Duncan McArthur, Esq., Doctor of Medicine, retired Physician of the Fleet;

Sir John Webb, Knight, Director-General of the Medical Department of the Ordnance;

Sir James Robert Grant, Knight, Doctor of Medicine, Inspector-General of Hospitals;

John Gunning, Esq., Inspector-General of Hospitals;

John Robert Hume, Esq., Doctor of Medicine, Inspector-General of Hospitals;

Sir John Richardson, Knight, Doctor of Medicine, Inspector of Hospitals and Fleets;

Benjamin Fonseca Outram, Esq., Doctor of Medicine, retired Inspector of Hospitals and Fleets;

Robert Perkins Hillyar, Esq., retired Inspector of Hospitals and Fleets;

Sir George Magrath, Knight, Doctor of Medicine, retired Inspector of Hospitals and Fleets;

Sir John Liddell, Knight, Doctor of Medicine, Inspector of Hospitals and Fleets;

Henry Franklin, Esq., Inspector-General of Hospitals;

James French, Esq., Doctor of Medicine, Inspector-General of Hospitals;

Stephen Woolriche, Esq., Inspector-General of Hospitals;

Charles Renny, Esq., Superintending Surgeon on the Bengal Establishment of the East India Company's Service;

B. W. Macleod, Esq., Doctor of Medicine, Superintending Surgeon on the Bengal Establishment of the East India Company's Service;

John Wylie, Esq., Doctor of Medicine, Inspector-General of Hospitals on the Madras Establishment of the East India Company's Service; and

Charles Doyle Straker, Esq., Doctor of Medicine, Superintending Surgeon on the Bombay Establishment of the East India Company's Service.

THE ATMOPYRE, AND ITS PRACTICAL USE AS A SOURCE OF HEAT.

A VERY ingenious mode of burning a mixture of coal-gas and air has been recently suggested by Mr. D. O. Edwards, surgeon; the object of which is to economise heat, and produce, without waste of fuel, a maximum of heat at a minimum of expense. For this purpose Mr. Edwards employs a small cylinder of pipe-clay, varying in length from two to four inches, perforated with holes the fiftieth of an inch in diameter, in imitation of the gauze of Davy's safety-lamp. The cylinder has a circular opening at one end, which fits exactly upon the burner No. 3, commonly used by gas-fitters. Gas is introduced into the interior of the cylinder, with the air of which it becomes mixed, forming a kind of artificial fire-damp. This mixture is ignited on the *outside* of the vessel, and it burns entirely on the exterior of the earthenware, which is enveloped in a coat of pale blue flame. The clay cylinder soon becomes red hot, and presents the appearance of a solid red flame. All the heat of combustion is thus accumulated on the clay, and is thence diffused by radiation and connection.

A cylinder of this kind, called by Mr. Edwards "a hood," is heated to dull redness in the course of a minute; but an aggregate of "hoods" placed in juxtaposition, and enclosed in an earthenware case, are heated to an orange colour, and the case itself becomes bright red. The case is fire-proof, being made of two-thirds Stourbridge clay and one-third "frit," or Stourbridge bricks pulverized; and the hoods are best made of a proportion of one-third China clay to two-thirds common pipe clay: they are blackened by one-third the proportion of black oxide of copper. For all common purposes, two-thirds of

fresh pipe clay, with one-third of pipe clay already burnt, would be thoroughly efficient.

As to economy, Mr. Edwards tells us that each hood consumes five-sixths of a cubic foot of coal-gas per hour, and a battery of eight hoods (consuming about seven cubic feet of gas) is sufficient to warm a good-sized room measuring about 4000* cubic feet, at a daily expense of about sixpence.

The numerous perforations in each hood, amounting to 90 on the average, secure a due supply of oxygen and the perfect combustion of fuel, the products of which may be entirely carried out of the room by a pipe attached to the apparatus. In this way, also, the warming may be conjoined with ventilation. Too much air must not be admitted among the hoods, for this would have the effect of cooling and reducing the amount of heat. Coal gas requires about 12½ times its volume of air for complete combustion. Any quantity of air beyond this proportion, acts as a vehicle to carry off the heat, and prevents its accumulation to a high intensity.

An earthenware case enclosing a battery of twelve hoods, becomes heated to 400° or 500°, and thus forms a safe and constant repository of heat. This may be placed in an outer case of china, terra cotta, or common ware. The fresh air is brought from the outside of the house through a large pipe about six inches in diameter, which communicates, by means of a valvular iron plate, with the space contained between the two cases. The outer case being perforated at top and bottom would allow a current of air to traverse it,—to become heated by contact with the inner case, and thus diffuse an equable temperature through an apartment. Each corner of the room might have its warming apparatus; while the supply of air, and therefore of heat, might be controlled by a valve in the iron pipe which brings it from the outside.

•• There is nothing new in the principle of the atmopyre. Chemists have been for some years in the habit of burning coal-gas mixed with air by the aid of a metal cylinder having a wire gauge top. Mr. Edwards has suggested the use of clay for the purpose of retaining and diffusing the heat. So long as the products of combustion are carried out of the apartment, this mode of procuring warmth from gas is safe, cleanly, wholesome, and unobjectionable. The question of its relative economy has yet to be settled by a practical application of the atmopyre on a large scale.

It does not appear very clearly from the

* A room 20 feet long by 15 wide, and 13 feet high, would have nearly this capacity.

description, how the aggregate of hoods are arranged with respect to the *first* which should fit the gas-burner exactly. Mr. Edwards tells us they should be placed in "jurisdiction." Some additional information on this point is desirable, also where the hoods may be seen or procured.

It appears to us that the plan of warming suggested by Mr. Edwards will be found highly useful if a sufficient supply of gas at a cheap rate can be procured.

STATISTICS OF POISONING.

A RETURN has been published relative to the number of poisoning cases tried in the United Kingdom from 1839 to 1849 inclusive. The number of persons tried for this crime during the above period, at the Central Criminal Court, has been 33, of whom 18 were men and 15 women; 16 were tried for murder, of whom five were convicted, and 17 for attempt, of whom 10 were convicted. In the Home circuit 8 women were tried for murder by poison, three for attempt to murder, and two men as accessories before the fact. The number of convictions was three. In the Midland circuit 11 women were tried for administering poison, of whom four were convicted. The number of men tried was six, all of whom were acquitted. In the Norfolk circuit 22 cases of poisoning were tried, in 12 of which the prisoners were female. The number of convictions was nine. In the Northern circuit the number of males tried for poisoning was 15, and of females five, the number of convictions being 14. In the Oxford circuit 17 cases of poisoning were tried, in nine of which the prisoners were women. The number of convictions was three. In the Western circuit, in 12 out of 22 cases of poisoning tried, the prisoners were women, and conviction took place in ten. In the county of Durham there have been no trials for poisoning. In the county palatine of Lancaster, out of eight cases, seven were of women, and conviction was obtained in five. In the North Wales and Chester circuit the number of persons tried for poisoning was 16, of whom 11 were women. The number of convictions was five. In the South Wales circuit five prisoners were tried for poisoning, two of whom were women. Conviction was obtained in one case only, in which a man and woman were implicated.

In Scotland the total number of trials for poisoning, from 1839 to 1849, was 15, in ten of which the prisoners were women; and in seven, convictions were obtained. In Ireland 31 women and 25 men were tried for poisoning during the same period, and convictions were obtained in 14 cases. The largest number of cases occurred during the year 1849, the number of cases being

13 (seven men and six women), the average of the other years being 4·3, in the proportion of 1·8 men to 2·5 women.

THE ASIATIC CHOLERA.

Alexandria and Cairo, August 7.—Several cases of cholera have occurred both at Alexandria and at Cairo, and there is every probability of another visitation of the disease to this country. Letters from Alexandria of the 8th inst. announce that in that city there were eight cases on that day. At Cairo, where it had also broken out, the number of cases averaged from 30 to 35 daily. The Viceroy, who, considering his station and the influence he exercises over the masses, should show more firmness, took to flight from Cairo as soon as the cholera made its appearance there. His Highness would not even come to Alexandria, but ordered a steamer and a frigate, well provisioned with stores of every description, to meet him at Damietta, to which town he proceeded, down the Nile, and there embarked for Rhodes on the 6th. Some cases of cholera had also occurred at Suez among people who had arrived there from Cairo.

Cuba and the Hawaiian, July 27.—Much anxiety is felt, and a great degree of uncertainty exists, as to the progress of the cholera in the interior of the island, and as to its probable effects upon the next and subsequent crops. This disease has not yet become general, but it continues to spread in various directions, and its ravages in many cases have been appalling. On several estates the destruction of life among the negroes amounts to 25 and 30 per cent., and in some cases even 40 and 50 per cent. of the whole number, and the most efficient are generally the victims. Should the disease diffuse itself throughout the island, the loss of life among the slave operatives would in this ratio probably not be short of 100,000 to 125,000. Even at the present average rate of mortality on the estates, the estimates as to the ultimate destruction of life among the negroes, in the event of the epidemic becoming general throughout the interior, are not less than 70,000 or 80,000. The period of the year is, unfortunately, not favourable for checking the malady. The labourers carried off are an irreparable loss, because there is no source available at present from which they can be replaced.

Malta.—The cholera still pursues its deadly course. Many hope it is on the decline, but it is to be feared that it is only subsiding in places where its ravages have been most severe, to commence in places hitherto free. Within the last few days we have had cases more frequent in Valetta, though as yet not very numerous. The progress

of the disease is dreadfully rapid. On Thursday afternoon Captain M'Queen, of the Royal Artillery, who has but recently joined the garrison, was attacked. At half-past 2 A.M. on the following morning he breathed his last, at the early age of 27 years.

Schleswig.—It is reported that cases of cholera have occurred among the soldiers of the Danish garrison in Schleswig.

Brunswick.—The cholera has been making some fearful ravages in Brunswick since the month of June. According to official reports, as many as eight hundred persons have died.

London.—The latest returns of the Registrar-General show that there is no appearance of an outbreak of malignant cholera in London. The deaths from this disease last week, when the total mortality was considerably below the decennial weekly average, amounted to only eight; and of these, six occurred among children.

Diarrhoea infantum is still very prevalent and fatal. Out of 139 deaths from diarrhoea, there were 118 among children under fifteen years of age.

THE MALIGNANT CHOLERA OF 1832 AND 1849 COMPARED.

WITH reference to the epidemic of 1832-3 we must take the statement as we find it made to the Privy Council, from which it appears that in London the attacks were 14,144, and the deaths 6,729; the population of London then being 1,681,641. From data given in the appendix, it is estimated that in 1848-9 the attacks were about 30,000, and the deaths 14,601; the population at that time being 2,206,076; so that in the last, as compared with the former epidemic, the deaths were more numerous than the attacks, while the attacks were more than double;—or, to state the result more precisely, in the epidemic of 1832-3, one person died in every 250 of the inhabitants, or 4 per cent.; whereas, in 1848-9, one person died in every 151 of the inhabitants, or 66 per cent.: the mortality, therefore, in 1832-3 was about two-fifths less than in 1849, which is the same as to say that in proportion to the population, about 5,800 more persons perished of this epidemic in London in 1849 than in 1832.

In England and Wales in 1832-3, the attacks are stated to have been 71,600, and the deaths 16,487.—*Board of Health Return.*

THE TENDENCY OF CHOLERA TO RE-VISIT THE SAME HOUSES AND STREETS.

As was anticipated and predicted, cholera, during its recent visitation, returned to the same countries, and the same cities and

towns, and even the same streets, houses, and rooms, which it ravaged in 1832. It is true that many places have been attacked in the recent, which escaped in the former epidemic; but very few indeed that suffered then have escaped now. In some instances it has reappeared on the very spot in which it first broke out sixteen years ago. The first case that occurred in the town of Leith in 1848 took place in the same house, and within a few feet of the very spot whence the epidemic of 1832 commenced its course. On its reappearance in the town of Pollokshaws, it snatched its first victim from the same room and the very bed in which it broke out in 1832. Its first appearance in Bermondsey was close to the same ditch in which the earliest fatal cases occurred in 1832. This return to its former haunts has been observed in several other places, and the experience abroad has been similar. At Groningen, in Holland, the disease in 1832 attacked in the better part of the city only two houses, and the epidemic broke out in these two identical houses in the visitation of 1848.

CONTAGIOUSNESS OF CHOLERA.

L'UNION MEDICALE, in one of its leading articles, deprecates the declaration of the contagiousness of cholera by the Academy of Medicine, on the ground of public alarm. Many sittings of the Academy have been devoted to the discussion of the question, and the result is that the proofs of contagion outweigh those of non-contagion. The editor observes, however, that this is the last question that should have been raised; that the attention of the Academy would have been better occupied by the discussion of the various modes of treatment which have been advanced, and the selection of some one plan which should receive public confidence.

We do not concur in this opinion of our valued contemporary: we regard the question of the mode of propagation of this disease, of the very first importance in reference to preventive measures. We know from sad experience that the disease is more amenable to prevention than to cure; and this, in so fearful a scourge, is a most acceptable mitigating feature, and one not to be met with to the same extent in many other epidemic diseases. X

THE MAHA MURREE, OR INDIAN PLAGUE.

THE last Indian mail brings the intelligence that the Maha Murree, or certain death, has again broken out in the hills of Gurhwal and Kamaon. This disease, which has all the appearance and symptoms of the plague of Turkey, is so infectious, or believed to be so by the hill tribes, that it used to be the custom to taboo a village

in which the disease had shown itself, to draw a cordon around it, beyond which, if any of the unhappy residents of the infected place dared to creep out, he was shot like a mad dog. The hills in which this infection almost always shows itself are those at the foot of the great snowy ranges; it disappears as it approaches the outer hills towards the plains; such as the Landour and Gagur Ranges. In Gurhwal and Northern Kemaon it takes a most virulent form, and the visitors of Nynee Tal and Almorah should hesitate in making the usual visits to the snowy ranges whilst this plague is said to be raging in the intermediate country, particularly British Garhwal. The Maha Murree is believed to be highly infectious: it commences with most violent fever, which is soon followed by swellings in the arm-pits and in other parts of the body; it destroys the infected in twenty-four hours generally, though there are some instances where the sufferer has lingered a few hours more. It is supposed that not one in a hundred of those attacked recovers.

MORTALITY ON THE AFRICAN STATION.

FROM a return made up to the year 1845, which is the last we have seen, it appears that the annual ratio of mortality in the African squadron for the period of twenty-one years then terminating, was 58 per thousand; that in the West Indies being 18, in the East Indies 15, and on home stations 9.

THE GENERAL BOARD OF HEALTH.

THE Queen has been pleased to appoint Thomas Southwood Smith, M.D., to be a member of the General Board of Health.

The General Board of Health have appointed Mr. Charles Macaulay, formerly clinical clerk to Sir Benjamin Brodie, and Lecturer on Medical Jurisprudence at St. George's Hospital, to be Assistant-Secretary to the Board.

ON ACUTE POISONING WITH PREPARATIONS OF GOLD, AND ITS TREATMENT. BY DR. HANNON.

THE salts of gold, more particularly the chloride, are, according to Dr. Hannon, among the most dangerous of the metallic poisons.

These salts, administered in very small doses, promote the activity of the digestive functions. A slight increase in the dose excites irritation of the mucous membrane. Administered in large doses, the vascular and nervous systems are excited; painful priapism, headache, delirium, and severe gastro-enteritis ensue: death rapidly follows, unless an antidote be speedily given. The antidote *per excellence* is proto-sulphate of iron. A chloride of iron is formed,

and the gold is precipitated in a metallic state extremely divided, and perfectly inert. Vomiting is then to be promoted, and inflammation or other symptoms treated as they may arise.—*La Presse Méd.* x

UNIVERSITY OF LONDON.—FIRST EXAMINATION FOR THE DEGREE OF M.B., 1850.

First Division.

THE HONOUR OF KNIGHTHOOD CONFERRED ON DR. OUTRAM.

THE Queen has been pleased to direct letters patent to be passed under the Great Seal, granting the dignity of a Knight of the United Kingdom of Great Britain and Ireland unto Benjamin Fonseca Outram, of Hanover Square, in the county of Middlesex, Doctor of Medicine, Retired Inspector of Hospitals and Fleets, and Companion of the Most Honourable Order of the Bath.

THE CLASSICAL EXAMINATION AT THE ROYAL COLLEGE OF SURGEONS.

THE Court of Examiners of the Royal College of Surgeons have just announced that in future candidates for the Fellowship of the College may present themselves for the examinations in the Greek, Latin, and French languages, and in the elements of mathematics, at any period after having attained the age of eighteen years.

OBITUARY.

DR. TWITCHELL, U.S.

DIED, in Keene, N.H., on Sunday, May 26, Amos Twitchell, M.D., aged about 70

years, for more than forty years one of the most eminent physicians and surgeons in New England. A great number of physicians in the United States cherish a remembrance of him as their highly esteemed preceptor and friend. Dr. Twitchell graduated at Dartmouth College in 1802, studied medicine with the late Dr. Nathan Smith, at that time and for many subsequent years a professor in that college, and obtained a medical degree in 1805. He soon after settled in Keene, where he ever afterwards resided, and in a very short time rose to eminence in his profession. He has received repeated proposals to accept of a professorial chair, which he has always declined. He has often been elected president of the New Hampshire State Medical Society, and was an associate of the Philadelphia College of Physicians. He was a prominent member of the National Convention which adopted the constitution of the National Medical Association, took an active part in its first organization, and he evinced a lively interest in its objects and its success.

ROBERT CLARKE EDWARDS, ESQ., M.D.

On the 19th inst., at his residence, No. 90, Oxford Terrace, Hyde Park, Robert Clarke Edwards, Esq., M.D., aged 37.

DR. WILLIAM OGILVIE PORTER.

On Thursday, the 15th inst., in Portland Square, Bristol, Dr. William Ogilvie Porter, aged 76.

JAMES SNELL, ESQ.

On the 6th ult., at Kingstown, St. Vincent's, West Indies, James Snell, Esq., surgeon, in his 55th year. He was a man of great and varied talents, energy of character and purpose, and of great zeal and probity in the faithful discharge of duty, in whatsoever he undertook.

ON THE EMPLOYMENT OF FORCED FLEXION FOR ARRESTING HÆMORRHAGE IN WOUNDS OF THE PALMAR ARCH. BY E. DURWELL, GUEBWILLER (HAUT RHIN).

M. DURWELL prefaces a case of wound of the palmar arch by some general observations on the modes of treatment which have been advised in this accident, and points out certain known objections to each. The following abstract presents the chief features of the case, and M. Durwell's subsequent observations:—

A woman fell from a ladder, having a bottle in her hand. The bottle was broken, and fragments pierced the palm. M. Dur-

well, on arriving at the poor woman's cottage, found the palmar arch wounded; and he had no means of securing the artery. While controlling the hæmorrhage by pressure on the brachial artery, the following sentence in M. Malgaigne's "Anatomie Chirurgicale" occurred to his mind:—"The only points at which obliteration of an artery can be obtained by position alone, without the aid of external compression, are at the bend of the arm and knee—a fact which is of great importance in reference to the arrest of hæmorrhage." Acting upon this statement, M. Durwell immediately bent the arm on the forearm at an acute angle; the hæmorrhage was instantly arrested. Advantage was taken of the circumstance to effect a definite cure. The arm was retained in its flexed position by bandages, so that the pulsation of the radial artery was completely intercepted. The wound of the hand was treated as an ordinary wound, and, for the sake of precaution, compresses were laid over the course of the arteries of the forearm. The cure progressed favourably. On the third day, as the patient complained of the restraint of the posture, the arm was slightly extended, and it was noticed that a small portion of florid thin blood oozed from the wound. The arm was restored to its flexed position, and in a short time the vessels and the external wound had perfectly healed.

In this manner a wound, usually regarded as of a very serious character, was safely and speedily cured by a proceeding as simple and unobjectionable as has ever been proposed. It must be attended with success when employed in analogous cases, and, from its simplicity, should be tried in the first instance in every case. M. Durwell observes justly, that it would be rash to make a more general application of a single fact, as there may doubtless occur complications, rendering its employment impossible or unadvisable; but, at the same time, he adds that this principle may be found, by further experiment, to be useful on other occasions, for the obliteration of the popliteal and humeral arteries. This principle he lays down in the proposition—"that in most arterial lesions of the forearm and leg, prolonged forcible flexion supersedes the ligature of the vessels."—*L'Union Médicale*. X

* * We find that the pulsation at the wrist is entirely stopped by firm flexure of the arm at the elbow-joint: hence hæmorrhage from the ulnar and radial arteries may be thus controlled.

PUERPERAL PERITONITIS.—DR. REESE'S NOTES OF HOSPITAL PRACTICE.

A SUDDEN irruption of this fever has appeared in the lying-in wards several diffi-

sent times, the epidemic character of which has been in every instance promptly arrested by abruptly changing the apartments to another floor of the house, having a different exposure to the external air, and in which a due ventilation could be secured. The wards in which the fever appeared were meanwhile thoroughly cleansed and purified by whitewashing, &c.; and not until thoroughly aired, and renewed by a change of furniture and bedding, have they been again occupied. Two or three weeks have been found a sufficient time to vacate the wards under such circumstances. The medical treatment has been various, and, in rather more than half of our cases, unsuccessful. The opium practice, when exclusively relied on, has uniformly failed. In no case has recovery taken place without bleeding; and yet, in several well-remembered examples, no advantage was derived from either venesection or leeching, although both had been liberally and judiciously employed. The same may be said of the mercurial treatment, with and without opium, and bloodletting, although all these remedies were used in every example of recovery; yet, in some instances, they all failed. The most numerous instances of success, however, were in those patients who, during the epidemic, were treated as follows:—Immediately after delivery, a combination of ten grains of calomel with ten of camphor was given. On the appearance of the characteristic rigor, when this occurred, or when without it other symptoms indicated an attack, the same dose was repeated, with two grains of opium. When pain and tenderness became distressing, and in the onset of the febrile excitement, a full bleeding at the arm was resorted to, the patient being placed in an erect position, and approaching deliquium being secured. If but little relief to the pain and tenderness followed this remedy, or these symptoms speedily returned, twenty or more leeches were applied to the abdomen; and, meanwhile, calomel and opium, in doses usually of from five to ten grains of the former, and one to two grains of the latter, were repeated every three or four hours, and in urgent cases more frequently. In these circumstances, a large blister plaster, covering the abdomen, and dressed with mercurial ointment on its removal, was found signally beneficial in several examples. The pytialism, when it occurred under this treatment, was but slight, and in no instance severe. The patients who recovered under this treatment used ice and iced water freely, all their drinks being cooled with ice. The extent to which bleeding was carried was various; two or three full venesections, besides leeching, having been sometimes called for during the first twenty-four

hours, and with uniform advantage, as the results proved. So also the calomel was varied in dose, and in the aggregate quantity, according to circumstances. Small, and even very minute doses, often repeated, were relied on in several cases, but every one of these proved fatal. So also scruple doses, with and without opium and venesection, were tried, but with less favourable results than the course above mentioned.—*Dr. Reese, in Amer. Journ. of Med. Sciences.*

LECTURES
ON THE
MEDICAL JURISPRUDENCE OF
INSANITY.

*Delivered in the Medical School of King's
College, Aberdeen.*

BY ROBERT JAMIESON, M.D.
Lecturer on Medical Jurisprudence in the
University.

LECTURE III.

General description of the insane state (continued). (a) The moral condition of lunatics (concluded).—Their selfishness, suspiciousness, timidity, and apathetic listlessness.—(b) The intellectual condition of lunatics—manifested in deranged voluntary power over the succession of thoughts, in delusion, imbecility, incoherence, and extravagant conduct—disturbed relation of will to thought. Delusions—their origin in violent mental impressions—their hold on the belief—their resistance to interfering doubts—their absorption of the attention—most distinctly defined in monomania—concealed delusion—delusions an insufficient test of unsoundness—divided into high and low. Subjects of exciting delusions—their insufficiency to produce happiness. Subjects of depressing delusions—Phobias—Panic—Hypochondriacal monomania—Nemomania, &c.—relative frequency of high and low delusions—modifications by sex, temperament, education, and bodily disease.

IN my last discourse I had commenced a general description of the insane state with the consideration of the moral condition of the insane. I described the peculiarities of that emotional derangement which is ordinarily a fore-warning of diseased intellect, and, in depicting the features of the fully developed disorder, alluded at some length to the morbid predominance of the selfish feeling, which, owing to the loss or depraved state of the sympathetic or benevolent affections, is so constantly observable in the insane. The consequences of this mental obliquity are for ever prominent in their language and behavior, and it leads besides to the unmasking of the evil passions of human nature, which, owing to the impaired voluntary control accompanying the disease, too frequently start up in ugly activity. In saying that the insane are

morally selfish, I use a term of very wide significance, which, as it were, epitomizes their moral condition, leaving very little to be added.

Suspicion is another feature which is pretty constant in the emotional aspect of the insane. Mistrust is said to be a natural characteristic of feeble minds, and to be the lot of those whose understandings have been but little cultivated; and it would also seem to be as natural a concomitant of mental disease. "The heart of the insane," says Esquirol, "cherishes no feeling but mistrust. This symptom increases with the progress of the disease, and augments in strength as the intellectual faculties are weakened. Yet notwithstanding their mistrust," continues he, "the insane have no foresight; they have no care nor inquietude for the future, but an extreme jealousy of every thing present."

This suspiciousness of mind, this constant imagining of evil, is exhibited in a multitude of delusions. Cabals and conspiracies are suspected to be formed against them by those whose good intentions there seems least occasion to doubt. Food is carefully inspected, lest it should be poisoned; to every unusual action in those around them a bad motive is attributed; and the over-heard common-places of ordinary conversation are twisted and tortured into an evil meaning towards their welfare. A female lunatic persisted in living solely on a vegetable diet during her illness, and no persuasion nor temptation could lead her to alter her resolution. After her recovery, I found that the reason of this conduct was, that she suspected the officials of the asylum in which she was placed to be in the habit of murdering the incurables, and victimizing the establishment with their bodies.

There are some cases in which the whole unsoundness seems to consist in unreasonable suspiciousness: it forms not an uncommon variety of monomania in advanced life. An old lady makes herself exceedingly miserable, by the baseless delusion that she is plundered and cheated by servants, neighbours, and indeed any one with whom she has had any dealings. Within doors, no number of locks and no ingenuity of fastenings are sufficient to give ease to her mind; every box and drawer is not only locked, but padlocked to boot; and when these are opened by herself, and every article is found in the exact relative position in which she had placed it, she has still the belief that her repositories have been entered, and her property changed for similar things of a less valuable description.

It is with the utmost difficulty that one

can satisfy a lunatic of the sincerity of words and intentions, and a request he looks upon as a snare. The superintendent of an hospital for the insane wished, for a special and very harmless purpose, to have the autographs of his patients. He found that he had undertaken a very difficult task in attempting to get them to comply with his proposal. He could persuade very few to subscribe their name without a great amount of trouble. Some signed hesitatingly; some repented when the deed was half done, or threw down the pen after they had taken it in hand; one signed his name upside down; another effaced his as soon as he had it completed; and many refused to have anything to do with such a dangerous proposal. The document was a very curious one in many respects, but not the least interesting feature in it was the evidence it contained of that suspiciousness of disposition on which we have been commenting.

So much suspicion is not compatible with a high degree of courage, and you will accordingly observe that an unnatural degree of *timidity* is one of the defects of the unsound mind. Patients in a state of maniacal fury may be found to encounter, blindly, any sort of danger, but all other kinds of insane persons are very easily alarmed. Those of them who are characterized as dangerous lunatics are more malignant than ferocious. The ferocity which, in times not long past, led to the imposition of chains and fetters on the insane, was the lie of ignorant, timid, and lazy keepers, or the result sometimes of their barbarity. You will find neither whips, chains, nor danger, within the walls of any of our British asylums.

An *apathetic listlessness* is another prevalent mood in the insane, though one of a negative kind, having its origin in a general anæsthetic condition of the senses, combined with an enfeebled memory and abstracted or decayed attention. Unless in maniacal cases, in which there is a morbid degree of activity, the desire of action is generally lessened, often entirely lost. The sound body cannot endure the tedium vite of idleness, neither can the healthy mind brook want of occupation. A man must have some occupation to withdraw him from himself, or, says Pascal, he is necessarily unhappy. Now the insane are almost constantly occupied with themselves, to the manifest increase of their misery. The desire of employment is very difficult to be excited in them; they will not exert themselves either to be useful or to be amused; and curiosity, one of the marks of an active and healthy mind,

is, as in some of the lower savage races, very much in abeyance.

One hears a good deal of balls and parties in lunatic asylums, and we have wondrous paragraphs in newspapers, mere puffs by vain superintendents or silly directors, describing how extra-sane and supremely happy all the proceedings were, or if any slip were, how pleasantly cured. Now having seen not a few of such things in various places, I can assure you that no ball in a lunatic asylum was ever worthy of the name; as how could it be, with the absence of such necessary elements as health, humour, wit, activity and contentment? In making this remark, I by no means intend to reflect in an unworthy spirit upon such attempts; they are most highly to be praised, if judiciously managed and not injudiciously blazoned. Such is the listlessness of the great body of lunatics, that to succeed to get them either to occupy or to amuse themselves is the hardest employment of those who have them in charge, and the one for which the highest commendation is deserved. Ennui is not a pain felt by an unsound mind. The monomaniac's delusion is his constant thought and his sole thinking; his feelings are of one complexion; he is insensible to the language which would arise from an unvaried feeling in a healthy mind. Ennui is a hopeful complaint in the insane, for they are in a position, says Esquirol, which is adapted to render it like an active sensation that will usefully react upon their thoughts and affections.

The intellectual condition of lunatics.—In the analysis of the human mind, two things are observed to constitute mental consciousness, viz.—thought and will. The first represents that unfeeling train of ideas which have their origin in an accidental series of external impressions on the senses, or which, if not ab externo, are connected together by certain laws of association. They consist of instinctive inclinations, emotional feelings, intellectual perceptions, and primitive rational intuitions. The second (will) represents the consciousness which we have of a certain amount of power in controlling or affecting the succession of thoughts. This voluntary faculty does not create ideas, it merely selects, detains, and operates upon, any particular idea of the many that crowd upon the mind. It is by this relation of our will to thought, that thought becomes thinking; desire, action; and abstract mind, personality. The agency of the will is apparent in such processes as attention, judgment, and recollection, which are, in truth, voluntary contemplation, alternate and retrospective; but, indeed, the volun-

very faculty is the essence of all intellectual operations whatever.

Now, in the various forms of intellectual unsoundness, both these principles seem in every case to be affected, though it would be more strictly correct to say, that it is the relation of the latter to the former that is disturbed. The suppression of ideas is more rapid than natural in maniacal excitement, more slow than natural in melancholia (monomania with depression), and uncontrolled by its natural laws in dementia. The voluntary power over strains of thought is defective in all cases. In mania it seems overpowered by the force and rapidity of the current; in melancholia, enfeebled by the one vast and gloomy image that has dammed up the whole channel of thought; and in dementia, permanently impaired.

Such a condition of the mind may occasion diseased manifestations of any or all of the intellectual processes, and it would not be difficult to select examples of disordered sensation, perception, attention, memory, conception, and so forth, occurring in lunatics: but the defect which is most characteristic of insanity is, as I have formerly stated, an inability to exercise the faculty of comparison, so as to evolve judgment upon one or more subjects, that incapacity being a direct consequence of impaired voluntary power over thought. In addition to such other evidence of disease as misinterpreted sensations and conceptions, rivetted or distracted attention, and wayward and irresponsible memory, there is this distinct impracticability of judgment before there can exist an insane delusion.

When the intellectual signs of madness become apparent, the premonitory stage is past; the disease is fully developed. The morbid intellect of insanity is displayed in delusion, inexplicable conduct, mental feebleness, and incoherence of language,—pathognomonic features which I shall now successively discuss.

Delusions are very generally but not universally to be observed in lunatics. They are, as you will recollect, illusions and hallucinations, governing the conduct, despite the will, despite the reason. They are idealities accepted as realities. They are errors of perception consequent upon the disordered sensations and disordered fancies, to which a diseased state of the psycho-physical relation renders the mind liable.

Violent mental impressions are the chief originators of delusion. Take the following example, which I borrow from the plentiful store of Dr. Conolly's experience. A clergyman opened a letter that was handed to him and swallowed the seal. A

friend standing beside him said, jestingly, that it might seal up his bowels. This made a startling impression on the clergyman's mind; the notion of his bowels being sealed up was a horrible one, and spite of himself, kept forcible possession of his thoughts, engrossing his attention so violently that his will became unable to dispel the conception. The attention could not be brought to bear upon any other subject, and if removed for a little, constantly returned to the disagreeable idea, until at length the conception acquired all the force of an actual sensation, and came to be believed in as a reality. The power of instituting an efficient comparison on this point was lost. No quantity of purgative medicine, operating however naturally, could prove to him that his intestinal canal was not actually closed up. There was no judgment in the matter, and he became a monomaniac with this particular hypochondriacal delusion. Here, then, you observe, first, a diseased intensity of conception; secondly, rivetted attention; thirdly, diminution of the voluntary power over the thoughts; and lastly, abeyance of judgment and insanity.

A morbid impression thus completely established—converted into a delusion—has a stronger hold of the belief than any impression that an actual sensation could convey. A lunatic believes in his delusion more firmly than ever he held by the truth of any real object of sense. The possibility of being deceived he cannot admit; he will sooner admit all other accredited realities to be deceptive. Those senses which act soundly enough have no power to correct the error. Sir Walter Scott relates the case of a poor lunatic in the Edinburgh Infirmary, who fancied that he was living in great state and splendour, in a mansion of his own, his only unhappiness being, that all the dainties with which his table was supplied had the taste of porridge. The palate acted an honest part, but its appeal to the judgment was quite ineffective. Any degree of doubt, which may arise in an insane person's mind regarding the reality of his fancies, is of a peculiar sort, and exerts no influence, or only one of the most transient and feeble kind. "I had a species of doubt," says a recovered maniac, describing what were his feelings, "I had a species of doubt; but no one who has not been deranged can understand how dreadfully true a lunatic's insane imaginations appear to him, how slight his sane doubts." A patient of Dr. Conolly's was the subject of delusions which he occasionally suspected to be delusive, and yet he could not deliver himself from them. He supposed that he had entered into pecuniary engagements with a friend,

which would occasion his total ruin. His words were, "I know I have not, I could make oath that I have not, and yet I cannot get rid of the impression that I have; and I am continually haunted with the dread of coming to the workhouse." This idea had led his thoughts towards suicide. He had tried in vain, and frequently, to get rid of the delusive impression by the exercise of reason, and felt conscious of the want of some help. "I think," he would add, "that I must get my friend to write me a letter, assuring me that I have not made this ruinous agreement with him; perhaps that may convince me." "But," says Dr. Conolly, "in these cases, until the morbid state is removed, conviction seems inadmissible by the mind: a man will send for his banker's-book, see that he has a large balance in his favour, and persist in saying that he is not worth a farthing."

The delusion of a lunatic is not an occasional but a constant error of mental action. "It is the dominant idea in his mind," says Dr. Pagan; "it is not a subject which occupies no more of his attention than its interest would seem to claim. He does not merely think about it erroneously, but it is *ever* present to his mind; talking, he speaks of it; silent, he thinks of it; sleeping, he dreams of it. No other subject has a proportional share of his attention; he has no sympathy for other men's interests."

Monomania is the form of insanity in which delusion is most distinctly defined. In the other varieties it is frequently difficult to point out any fixed governing idea. The maniacal are in a state of delirious excitement, in which everything wears a strange aspect, and the judgment cannot be brought to bear efficiently on any one idea. Their delusions are constantly varying with surrounding circumstances, and have no marked persistence: an insane notion arises, disappears, and is replaced by some other idea equally unsound, and possibly inconsistent with its immediate predecessor.

In monomania there is one particular, fixed, and dominant delusion, or there are a set of relative subjects on which the patient always manifests his derangement. If he think himself a king, for example, he may be comparatively rational on all matters unless those which connect themselves with the idea of his royal condition. But even in monomania, a delusion absolutely and persistently single is a rarity; for, by and by, the intellectual blemish is well seen to be surrounded by other marks of unsoundness, no longer latent. It is not, as ordinarily stated, that one delusion produces more; that one maggot generates another; the single intellectual error extending its

influence like a morbid virus. I have already told you that partial insanity as opposed to general is not a true phrase: it is only the exhibition of unsoundness that is limited. The single delusion is but the first manifestation of a mind as wholly unsound, though less intensely, as that of the bewildered maniac. However, be this as it may, true it is, that, when you have a single delusion, the chances are that you will have many more evidences of disease. There are few monomaniacs in whom the mind acts with vigour and soundness on subjects even widely removed from that of their delusion.

An insane person sometimes seeks to conceal the existence of delusion. I believe I may add that he never succeeds. There are such things as concealment of the nature of the delusion; but that some delusion exists in the mind is always in some measure expressed in habits and conduct. The attempt at concealment is to be witnessed only in cunning monomaniacs, who have become aware that they are deemed insane. Monomania is, however, the very form of insanity which gives rise to judicial difficulties, and in which it is of the greatest importance that the existence and character of the dominant delusion should be clearly displayed. I have more than once known such a lunatic to conceal the cloven-foot so successfully as to impose upon a most competent and persevering examiner, who was ignorant of the particular point on which the power of rational discussion was impossible. The insane often appreciate the motives which ought to lead them to hide their aberration, and are well aware of the subjects on which it is necessary to exercise concealment, in order to pass muster as sound in mind, but for all this they seldom or never succeed in concealing their delusion when they are directly questioned regarding it. The most that a lunatic desirous of passing as sane can in general effect is not of himself to introduce the subject on which his judgment is alienated; but when he is expressly catechised upon it he either refuses to answer any queries regarding it, which is to him a very great effort, or he certainly stumbles in his replies, and makes evident the unsoundness of his understanding. An insane lady had so far imposed upon a philanthropic visitor of the asylum in which she was confined, as to lead to a private and influential representation to the sheriff that she was unnecessarily and unjustly deprived of her freedom. The sheriff accordingly called unexpectedly at the hospital, and had a private audience in order to satisfy himself of her condition. She answered every question in an rational style, so to afford no apparent grounds on which her liberation should be refused. Upon consulting the case-book,

however, he found that she was said to entertain the belief that she was the Duchess of Wellington, or at times the Baroness Rothschild. Having obtained the key to her mystery he held a second conversation with her, when, in spite of her anxiety to impose upon one whom she knew to have the power of terminating her confinement, she exhibited such evident insanity, that he left her apartment holding up his hands in amazement. She would not resist a direct interrogatory upon her rank of Duchess.

Common as delusions are amongst the insane, they are not prominent, nor possibly even existent, in every case of the disorder, and therefore the absence of delusion is no test of soundness. Delusion is merely one indication that the disease has extended to the intellectual faculties, and is therefore no test of mere imbecility, of moral insanity, or of the first stage of many cases both of monomania and mania.

It is usual to divide the delusions of the insane into *high* and *low*, or *exalted* and *depressing*, according to the mode in which they affect the patient's self-esteem. What is commonly called a depressing delusion may be combined with both mental and corporeal excitement, and a high delusion may exist with much apathy of mind and debility of body.

Most of the high delusions of the insane consist of ideas of imaginary rank and wealth; of over-estimation of mental and bodily powers, and of imaginations of a less sublimary kind, leading the subjects of them to consider themselves as inspired by Heaven. However exalted the insane idea may be; and however much calculated to render the possessed of it independent of the influence of immediate and surrounding circumstances, it is very seldom a source of happiness and comfort. Such high notions seem always to cast a shadow on the mind; there is a hollowness in the happiness such as interferes with the exalted fancies of feverish dreaming, and a frequent recurrence of moods of depression, which are little consistent with the professed state of beatitude. As a class, lunatics are persons experiencing a great amount of misery: the feeling of pleasure is rare amongst them; laughter is almost unknown, at least as the natural language of joyous emotions; and it is only among some of the imbecile that unhappiness is either expressed or seen in the countenance or the conduct.

The low delusions are of more various kind, and require more special description. In this list, prospective feelings of dread, retrospective and present suspicions, hypochondriacal miseries, and terrors of the future state of existence, form the most remarkable groups. The dread of being killed by their enemies, or of suffering death

by the hands of justice for some form of fancied guilt, is a common species of delusion amongst the insane (*thanasophobia*), and one which it is well to be aware is perfectly compatible with the desire of killing themselves, and which is indeed very usually associated with the propensity to self-destruction. Many are overshadowed by some impending and gigantic evil, vague, but dimly real and irresistible, which they cannot describe. Every object wears a threatening aspect; they feel terrors unaccountable; their hearts are sunk within them; tears are scarcely ever from their eyes; and their whole occupation is to watch for the bursting of the dark cloud that is to destroy them for ever (*panophobia*). Some live in the constant dread of poison mixed with their food, administered instead of drugs, placed upon their clothes, hidden in their beds, and poured into their ears, or administered per anum during sleep. Others labour under the fear of future want, and, with no ground for anxiety, believe that they are on the high road to destitution and beggary. Their past circumstances seem like an experience of purple and fine linen when compared with their present condition; and the future they regard as a vision of sackcloth and starvation: such misfortune has been brought about by enemies who have plundered and cheated them, or has come upon them, by the vengeance of heaven, as a punishment for sins. Domestic jealousy is not an uncommon character of the insane delusion, particularly amongst males. Men are also more subject than females to another imagination which is a frequent accompaniment of lunacy, — the conviction that they are the victims of a widely-extended conspiracy. Every one with whom they come in contact is sure to become concerned in the great plot which is hatching against them. Macnaughten, the lunatic who assassinated Mr. Drummond, was a monomaniac of this class. For many years he had imagined himself an object of persecution, first to the Jesuits, then to the whole body of Roman Catholics; these were latterly joined by the Police, and finally, he believed, by the whole Conservative party. There is a numerous class of the insane in whom strange bodily sensations give rise to the notion that they are the subjects of strange pathological conditions, or of actual physical metamorphosis (*hypochondriacal monomania*). The sexual organs are very frequently the subject of hypochondriacal delusions among the insane. Obstructions of the intestinal canal, displacement of viscera, the sensation of living animals within the cavities, and various monstrosities of external appearance, are also common imaginations in this class. Depressing delusions connected with

religious subjects are very frequent, particularly amongst the female insane. Such persons are beyond the power of salvation, are under the curse of the Deity, have committed the unpardonable sin against the Holy Ghost, have directly bartered their soul to the evil one for some worldly pleasure or advantage, or are actually already in the state of eternal torment. Witchcraft, and various forms of unseen agency, are other subjects on which the insane often manifest their lack of judgment. They have been permanently injured by the incantations and evil prayers of others; their thoughts, words, and actions, are not the effects of their own individual will, but are the devices of external machinations, or are the doings of evil spirits around them, or within them. Now and then a patient will be found who has the painful fancy that he is actually possessed by the Devil, that his soul has been taken from him, and that Satan himself has taken possession of his frame (*demonomania*).

Delusions are liable to be modified by such circumstances as sex, age, temperament, education, and bodily disorder. Depressing fancies are much more common than those which are called exciting. In 287 instances of monomania, I found that the low delusions amounted to 168; the high delusions to 76; and those which were of an indifferent order to 43. High delusions were more frequent in the male than in the female sex. The only temperament in which they relatively predominated over those of a low type was the sanguine: in all the others, particularly in the lymphatic or deteriorated sanguine, depressing imaginations were the more numerous.* High delusions have a tendency to be transformed into those of a depressing character. Education modifies the nature, but more strikingly the expression, of insane convictions. An intelligent person, for instance, will not be found styling himself "the fourth person of the Trinity;" nor will an educated female write her name "Margaret Rex." The sensations which compel an ignorant lunatic to express his belief that he has been bewitched, would, in one above superstition, lead to the notion that he had been brought under the influence of some kind of magnetic or mesmeric agency. Bodily disorder may, there is some reason to think, produce a modifying effect. Diseases of the lungs, or of the encephalon, are

* In 244 patients in whom the modifying influence of temperament was observed, the following ratios existed:—

	High delusions per cent.	Low delusions per cent.
Aggregate cases	31	69
Nervous temperament ..	30	70
Bilious " ..	26	74
Sanguine " ..	60	40
Lymphatic " ..	8	92

more likely to be conjoined with delusions of a high cast, than those of the kidneys or heart are. Almost all cases of insanity which are threatening apoplexy or paralysis, are associated with high delusions. In those cases, also, which are complicated with the peculiar paralysis of the insane,—an insidious general palsy,—exciting fancies, are nearly universally observable. Such persons, while they are scarcely intelligible, from defective articulation, while they are passing their urine involuntarily, and staggering with extreme difficulty from one chair to another, still have a shattered physiognomy of happiness. They are in a paradise of excitement, leading armies over Alps, or dispensing the riches of India. When death is making daily approaches upon them, they are in a state of miraculous health; and when they are in his very clutches, they are in the arms of victory, or the glories of Solomon's temple.

CASE OF ANEURISM OPENING INTO THE TRACHEA. BY DR. MINOT.

THE patient was a female, thirty-six years of age, who had had dropsy for fifteen years, and diseased heart for the last four. Five weeks ago, there was noted a hoarse cough, dyspnoea, wheezing, and at nights orthopnoea but without expectoration or palpitation. These symptoms increasing, she was suddenly seized with extreme dyspnoea, the inspiration being easy, but the expiration laboured and rattling; pulse 160, and very feeble; whole chest resonant on percussion, but with sonorous and sibilant rales in every part. From this attack she revived, after a copious expectoration of clear, viscid fluid; but soon had a second. The respiration continued somewhat rattling, and always had a peculiar tubular sound, which could be heard at a distance from the bed; she complained, also, constantly of a sense of oppression in the trachea. Nine days before her death there came on pleuro-pneumonia; but this seemed to be subsiding, when, after a slight fit of coughing, a torrent of blood poured from the mouth and nose, and she died instantly.

The specimen being shown by Dr. M., there is seen to be some ill-defined dilatation of the arch of the aorta, with disease of the parietes, but nothing that can be called an aneurism; upon the inner surface of the artery at this part there is a deep ulcer, four or five lines in diameter, and this had burst into the trachea just above its bifurcation; a red, fleshy little mass projecting into this last at the seat of perforation. The bronchi were full of coagulated blood, and there were also found pneumonia, pulmonary emphysema, old pericardial adhesions, and scirrhus.—*American Journal of the Medical Sciences*, July 1850.

ON SOME OF THE
MORE PRACTICAL POINTS
CONNECTED WITH THE
TREATMENT OF DEFORMITIES.BY EDWARD F. LONSDALE,
Assistant-Surgeon to the Royal Orthopaedic
Hospital.

(Continued from p. 191, vol. xlv.)

*Of the Treatment of Talipes Varus—
T. Valgus—T. Equinus—T. Calcaneus—
and T. Calcaneo Valgus.*

In my last paper I considered the treatment of talipes equinus and equino varus, in both of which it is necessary to divide the tendo-achillis; and in the latter sometimes the anterior and posterior tibial tendons, and, when very rigid and much shortened, the plantar fascia as well. I also described the mechanical means by which the foot was to be brought into its natural position, and of keeping it so afterwards.

There is a point I wish to refer to, before entering upon the treatment of talipes varus, which I omitted to mention when speaking of the division of tendons generally.—namely, a peculiarity that exists in the mode in which the tendon separates where it is found necessary to redivide it some time after the union of the first division. It will be found that it never separates with the decided “jerk” or “snap” that it does on the first division, nor is the same interspace left between the two ends. So little appearance is there of any division having taken place, that one unaware of the peculiarity I have mentioned would suppose such not to be the case, and would reintroduce the knife to make one or more attempts to ensure success: so constantly is this peculiarity met with, that it may be considered as a diagnostic mark of a previous operation having been performed.* A second operation may be required in cases where the patients neglect to attend to the after-treatment, or where the mechanical means are not properly and

efficiently applied to remove the deformity at a sufficiently early period to prevent the rigidity of the tendon returning before the deformity is removed.

The explanation of this peculiarity I have no doubt is, that after a tendon has been divided, not only do the ends themselves become joined together, but adhesions of the sheath to the adjacent portions, as well as to the surrounding cellular tissue, also take place, and which remain permanent after all thickening has subsided, and leave no appearance on dissection observable to the eye.

Of Talipes Varus.

Talipes varus is the true form of club-foot, of which all the other varieties may be said to be modifications.

Nature of the deformity.—Inversion of the foot, varying in degree from the slightest pointing of the toes inwards, to the extreme degree of inversion, where the anterior half of the foot brings the toes upwards, so as to be placed within a very short distance of the inner edge of the tibia. The os calcis is raised in an unnatural degree by the contraction of the gastrocnemius and soleus muscles, or by the original shortening of the muscle or tendon, or both, “in utero.” The other bones of the tarsus also lose their natural relative position to each other: thus the astragalus becomes displaced downwards and outwards in a position that the whole pressure of the weight of the body in walking falls principally upon this bone. This is made apparent in cases of long standing,—that is to say, where the patient has walked much, by the thick pad of fat and adipose tissue which nature forms as a soft cushion to protect the skin and parts beneath it from injurious pressure. The smaller tarsal bones, as well as the metatarsal bones, become also compressed, so as to diminish the transverse arch of the foot, the os cuboides and metatarsal bone of the little toe taking part with the astragalus in less severe cases in bearing the weight of the body. In very severe cases, as already stated, the foot is so much turned upwards and inwards, that the pressure falls only or principally upon the astragalus.

* I have found the above to be the invariable rule since I heard the observation made by my colleague, Mr. Tamplin. The tendon never separates at the first operation, no matter how many years after, the second may be performed.

ingential or non-
requently the
nentially

spasm of the one set of muscles over the other, or else to paralysis of the muscles on the anterior part of the leg, so leaving the foot to the action of those muscles of the posterior part of the leg, which, without being spasmodic, may, from want of any opposition, gradually draw the foot upwards and inwards.

The degree of severity existing in the congenital varus when the child is born is found to vary much: thus in some cases the foot may be said to be simply inverted, without any other alteration of its shape, the arch of the foot, either in its long or transverse diameter, not being shortened, and consequently unattended with any alteration in the relative position of the tarsal bones, the only alteration being that the astragalus is slightly drawn from its contact with the end of the tibia, and the os calcis being drawn slightly above its natural level: in these cases there is but little rigidity or contraction of the muscles, and the position of the foot admits of being easily redressed to a certain point by mechanical means only. In the severest forms of infantile varus, the foot becomes almost as much displaced as in those adult cases where the person has borne the weight of the body upon the foot for some years, causing the bones to be wedged together in every direction; the only difference being that in the infantile varus the transverse arch of the foot is not diminished, owing to the child not having yet walked. The tendons may be equally rigid in proportion to the child's age, and take an equally active part in keeping up the deformity. I stated in a former paper that in the non-congenital cases of varus, when dependent on paralysis, the feet never become so much deformed, owing to the condition of the limb never allowing the weight of the body to tell with a degree of pressure sufficient to compress the bones together, as occurs in the congenital adult cases where the limb is otherwise healthy. For the same reason you never meet with the thick pad or cushion on the inferior edge of the foot in the former, as in the latter cases.

Of the treatment of Talipes Varus.—

The first thing to be considered is the acting cause which immediately opposes the return of the foot to its natural position: and this will be found to exist in the permanent contraction (for such it may be said to have become) of those

muscles whose natural action is to turn the foot into the position in which it is found to be placed. The three principal tendons, then, that have to be divided, are the tendo-achillis, the posterior and anterior tibial tendons, and in some cases the tendon of the long extensor of the great toe, as also the long common flexor of the toes. The division of this latter tendon is rarely required, but may be in very severe cases, as well as in the paralytic cases of varus, where the toes become flexed in an extreme degree, owing to the paralysis of the extensors. The plantar fascia very often requires to be divided, owing to its shortening and extreme rigidity opposing any attempt to elongate the foot in its long diameter. Its division is often required in infantile as well as in more advanced cases of varus. In the former cases, however, the shortening of the fascia does not become apparent till the treatment has sufficiently advanced to enable the foot to be flexed in its natural position; it will then be found that the toes cannot be brought sufficiently upwards, at the same time that the arch of the foot is more prominent than natural, a condition that can be easily ascertained to depend upon the plantar fascia, by pressing the finger forcibly into the sole of the foot at the same time that the fascia is put upon the stretch, when a firm hard cord will be felt. I should recommend the division of the plantar fascia in all cases, whether infantile or adult, where it appears to offer the slightest resistance to the elongation of the foot, it being, I believe, one of the most unyielding parts of the body, and much more so than the proper ligamentous structure.

The alteration in the shape of the bones is little or none, which is a matter of surprise, when it is considered how much the relative position of the individual bones to one another is changed, as well as their points of contact bringing them under the pressure of the weight of the body in a direction quite different to that they would have to bear in the natural condition of the foot.*

* There is a very interesting specimen in the museum of St. Bartholomew's Hospital of a skeleton with double club-feet, showing very well the altered position of the bones. The os naviculare is pushed completely from its articular junction with the astragalus, and rests on its inner edge. The os cuneoides is also displaced from its connection with os calcis, resting also more on its inner than anterior edge. (Abstract)

The only bone, I believe, which is liable to become affected is the astragalus;—absorption may take place, causing a diminution in its size, more particularly of its anterior portion; produced no doubt by the constant pressure upon it in adult cases. The inner malleolus of the tibia will also be found in some cases diminished in size, caused no doubt by the constant pressure against it, either originally preventing its growth to its natural size, or causing its diminution afterwards.* This will of course weaken the joint, by depriving it of the support it naturally possesses in its perfect state, and be a cause of the return of the deformity, if the ankle-joint be not properly supported by mechanical means, when the patient begins to bear his weight upon the limb after the foot has been brought into position.

The ligaments take an active part in keeping the bones in the wedged position in which they are found in adult cases of varus, rendering it one of the most difficult parts of the treatment to get the foot flat, by the opposition they make to the unfolding of the arch: and until this be done the cure cannot be considered satisfactory; for when the patient begins to walk, he will be seen to tread more upon the outer than inner edge of the foot, and will gradually turn the foot inwards, and after a while cause a return of the deformity. The most difficult bones to redress are the os cuboides and the metatarsal bone of the little toe. It must be the ligaments that oppose the replacement of the bones, for only one other cause could,—viz., anchylosis, and this I have never seen yet, nor do I think it likely to occur.

In all cases of varus, whether slight or severe, *the foot must be brought completely out of its state of inversion, so that the great toe may be in a straight line with the tibia, and the sole of the foot be rendered perfectly flat*, before any attempt at flexion of the ankle-joint be made. If this be not attended to, the deformity will never be removed, for two reasons—in the first place, the joint cannot be flexed to an extent sufficient

to allow of the heel being brought completely to the ground; and in the second, no after attempts to flatten the arch of the foot will be successful.

I shall now describe more in detail the various steps in the treatment of varus, and I shall take a severe form in the adult, in illustration.

It is impossible to give a *decided opinion* as to the length of time it may take to treat the severe form of congenital varus that is met with in the adult; for, as I have already stated, the great difficulty is, to unfold the arch of the foot, to bring the tarsal and metatarsal bones out of their wedged into their natural position, and the amount of resistance that may be offered cannot be ascertained till the treatment has made a certain advance: as a general rule, the older the patient the longer the case will take to treat: there may be a difference, however, in cases of the same age, which may be referable to the severity of the form of varus. There is also a difference in infants, some cases being much more amenable to treatment than others. As far as my own experience has gone, I should say the average limits of time it takes to treat cases of confirmed congenital varus in adults, and much after the age of puberty (and by *treatment*, I mean not the *partial* removal of the deformity by which the patient is enabled to put the sole of the foot to the ground, the foot itself still being twisted, but the *complete* restoration of the shape of the foot, in which all trace of deformity is removed), is from eight to twelve months, and in some cases more. In infants from two to four months old, the time required will be about the same number of months, either two and four, according to the degree of severity of the deformity; in some even less, when the varus is but slight, and in others a longer time, when very rigid. As a general rule, an opinion may be pronounced as to the case being one of an obstinate nature by the appearance the foot presents, as well as by the degree of rigidity it offers to the hand when attempts are made to move it towards its natural position: some will be found to be much more yielding than others, and will therefore offer less resistance. The appearance of the dorsum of the foot will indicate the extent to which the bones are wedged inwards towards the sole, by being more prominent, and

tion has also taken place of the anterior and outer parts of the astragalus, and os calcis. The other bones are of their natural size and shape.

† I have a case under my care now, of congenital varus in an adult, where there is a complete absence of the inner malleolus, there being no trace of any projection now that the foot is brought into its natural position.

presenting an irregular and knotty surface, instead of the smooth one the dorsum of the foot naturally possesses. This difference is observable in infants also; in some cases the tarsal bones project from the dorsum of the foot much more than in others, and are always a longer time under treatment.

Of the division of the tendons in varus.

—The first stage in the treatment of talipes varus is that occupied by bringing the foot outwards and downwards from its inverted position till it is in the state of extreme extension, the great toe being in a line with the inner margin of the tibia. To admit of this being done, the tendon of the posterior and anterior tibial muscles must be divided, and in extreme cases, the flexor communis digitorum, and the extensor proprius pollicis. The mode of dividing these tendons I have already described in a previous paper. When the plantar fascia takes part in producing the deformity, by shortening the foot, it must be divided also. I believe that in very severe and rigid cases advantage will be gained by trying to bring the foot outwards by mechanical means as much as possible before the tendons are divided, in order to advance the foot a stage, the object of which is, that the most obstinate rigidity offered by the bones and ligaments will be reached at an earlier period after the tendons are divided, and before union of their divided ends can have become sufficiently firm to act a second time as an opposing cause, which I am inclined to think may be sometimes the case, with these tendons, as well as with the tendo-achillis (which latter tendon is not divided in the first stage of the treatment to this account)—viz., that by the time the foot were in a position to be flexed it would have become so firmly united as to require redivision. In infants, in most cases, the tendo-achillis may be divided at the same time with the other tendons, for the foot may be everted before the union has become sufficiently strong to oppose the flexion of the foot upwards; but here, also, should the form of varus be more than ordinarily rigid, I should recommend its division at a second operation, as in the adult, as it will save after trouble, as well as the necessity of a redivision of the tendon.

The mechanical treatment required in

the first stage of varus.—After waiting four or five days in infants, and a week in adult cases, to allow the wounds to heal, and the union of the tendons to have commenced, abduction of the foot may be commenced in the following manner:—The leg must be evenly rolled from the toes upwards, to the knee. A long straight wooden splint, extending half way up the thigh, and for about eight or nine inches below the ankle, and of a width corresponding to the width of thigh and leg (that is to say, the upper part is to be as wide as the thigh, and gradually diminishing to the thickness of the ankle below), is to be placed outside the limb. The object in shaping the splint in this manner is, that it is less liable to slip from its position than if it were made of one uniform width. A firm pad is placed beneath the splint, being made of much greater thickness opposite the outer ankle, in order to throw the splint well off from the foot, to enable the straps that pass round the toes and instep to act with greater advantage. This pad should not extend below the outer ankle to avoid pressure against the edge of the foot itself. The splint is fixed to the thigh and leg by five or six broad webbing straps placed at intervals, the lowest one being low down, close to the instep: an inside splint is sometimes of use also, attached by back straps to the outer one, when there is a difficulty in preventing the outer splint slipping round the front of the limb. The lower end of the outer splint is notched in three or four places, or may have slits made in it to pass two or three straps round and through. These straps are made to act upon the foot in the following manner: the lowest one passes round the ball of the great toe; the one immediately above it round the instep; the third round the bend of the ankle and over the heel behind. Before these straps are tightened the foot is to be everted as much as the rigidity of the parts will admit of, when the straps are to be fastened by means of the buckle to retain the foot in this position. The straps are to be tightened by degrees so as to bring the foot gradually more and more outwards every second or third day, accordingly as the patient may be able to bear the pressure, care being taken that irritation of the skin be not produced either on the outer ankle or over the ball of the great toe, and if

such be the case, all the straps must be loosened till the skin recovers itself.

As soon as the foot has become everted from its original deformed position, sufficiently to be in a straight line with the leg, examination must be made to ascertain the condition of the tarsal and metatarsal bones; and if the cuboid and metatarsal bones of the little toe be found projecting towards the sole of the foot, so contracting the transverse arch, means must be taken to press them upwards towards their natural position. These means are by placing pads beneath the sole and on the dorsum of the foot in such a position that they may press the outer edge of the foot upwards and the inner edge downwards. This is best done by first placing the foot in the Scarpa's shoe. This, as before stated, is often one of the most tedious parts of the treatment, for it must be persevered in till the sole of the foot be rendered quite flat, requiring frequent alteration in the position of the pads, and will often tax the patience and ingenuity of the surgeon.*

In infantile, or cases more advanced, but still under the age of puberty, these screw pads are not so frequently required; for there has not been that degree of pressure made upon the bones of the feet by the superincumbent weight of the body to fix the bones in the wedged position which I have just been describing.

Of the second stage of the treatment of varus.—Presuming the foot to have been brought into a straight line with the leg, and the wedged condition of the arch of the foot having been sufficiently unfolded, so that the sole of the foot is rendered flat, the foot is now in a condition to allow of the second stage of the treatment to be proceeded with, which is that of flexing the ankle-joint and bringing the heel down. In order to do this, the tendo-achillis has to be divided, which operation I have already described in a previous paper. At the end of five, six, or seven days, according to the age of the patient, the limb may be placed in the Scarpa's shoe, taking

care that the straight line of the foot and leg be still preserved; the ankle-joint is now to be flexed every second or third day, by turning the screw at the ankle, each time very gradually. As a general rule in adult cases, this flexion of the ankle will occupy about six weeks or two months, and becomes in most cases the shortest stage of the treatment, though unforeseen circumstances may occur to interfere with this part of the treatment, so as to allow the union of the tendo-achillis to have become so rigid as to prevent the heel being brought down, and to require a second division of the tendon before the cure is completed.

Of the third stage of the treatment of varus.—The foot having been now brought into position by means of the Scarpa's shoe or other mechanical means the surgeon may please to employ, the next thing to be done is to fix it in such a manner that the patient may begin to make attempts to bear his weight upon it in walking, and this is to be effected by means of a boot and iron so made, that the foot is prevented being turned inwards and the heel being drawn upwards. The principal points to attend to, and which I have already described in a previous paper, are, to see that the boot is large enough and wide enough to prevent the toes being cramped. The part of the boot opposite to the bend of the ankle should fit sufficiently tightly to keep the heel well down. Further support is given to the ankle by means of a double iron, one on each side of the leg, extending up to the knee, with joints opposite the ankle made to lock at their posterior part, and so prevent the heel from being drawn upwards. A broad ankle strap is also required, passing round the outer ankle and inner iron. This boot must be worn in bed as well as in the day-time, the first month or six weeks, to guard against any recontraction of the tendo-achillis. Another important point to attend to, is to work the ankle-joint frequently in a state of flexion; either by the patient himself placing the foot flat upon the ground and bending the knee forwards, or by a second person taking hold of his foot and forcibly flexing it upwards. This practice should be followed daily to overcome the rigidity which naturally exists, as well as to overcome any tendency there may be for recontraction of the tendons.

* There have been two or three cases lately in the Orthopedic Hospital, under the care of my colleague, Mr. Tappin, in which the difficulty of unfolding the arch has been immense, and which have required great pains and trouble to bring the feet into the flat condition, causing the cases to occupy a length of time only known to those who have great experience in the treatment of these cases.

In infantile varus, the same powerful means are not required to bring the foot into position, though the same rules hold good as in adult cases—viz., that the foot should not be flexed till it be brought in a straight line with the leg. A small Scarpa's shoe may be employed, or other mechanical contrivance which gains the desired end. A boot with a very light thin iron may be required in some infantile cases as well as in adult, where much rigidity remains or tendency to recontraction of the tendo-achillis. Weakness of the knee-joint often exists in these cases of infantile varus, which is evidenced by the leg rolling inwards, causing the foot to turn in the same direction, and giving the appearance of the foot still being deformed. This is to be obviated by carrying the iron above the knee, and attaching it to the thigh by means of a broad leather strap, and if the inversion be extreme the iron should be carried still higher up to the hip and attached to the pelvis. It is to be worn till the child gains sufficient power over the muscles to prevent the knee rotating inwards.

Of Talipes Valgus.

Nature of the deformity.—Eversion of the foot, with flattening of the arch, causing the foot to be much wider than natural, owing to the tarsal and metatarsal bones being spread out to the utmost in severe cases, instead of being wedged together as in the cases of varus just described. The inner edge of the foot becomes rounded, and projecting inwards; the outer edge appears much widened, and almost inclined to turn upwards; the os calcis appears longer than natural, owing to the flattening of the foot bringing the tibia and fibula more forwards and inwards. This condition of the foot is produced entirely by the want of power in the ligaments to keep the bones in their natural position. The opposite set of muscles is now in action to that in the talipes varus—viz. those muscles that turn the foot outwards and upwards,—these are the peronei and long extensors of the toes. Their tension is more marked than the tibialis posticus and anticus, owing to their position admitting of more displacement of the tendons, and therefore making them more prominent, and more easily felt. The tendo-achillis is not concerned in the simple valgus, although the natural facility of bending the ankle-

joint does not perfectly exist; this is owing, however, to the altered position of the tibia, by the astragalus being pushed so much forwards and outwards. Talipes valgus may be congenital: it is, however, more frequently noncongenital, and produced most commonly by carrying heavy weights, and being constantly on the feet.

Of the Treatment of Talipes Valgus.

If there be the least rigidity about the joint, combined with marked resistance of the tendons, mechanical treatment only will not succeed in removing the deformity. In slight cases, however, where these are not tense, and the deformity of comparatively short standing, there will be no occasion to divide the tendons: the following treatment will then be found sufficient to effect the cure. If the flattening of the foot be only slight, a piece of cork placed on the sole, in the inside of the foot, shaped in a manner to press principally beneath the astragalus and cuneiform bones, the object being to support the arch of the foot at the part where it is most inclined to sink. The cork should not be made of the full thickness at first, otherwise it will make painful pressure; it should be thickened by degrees, until the arch of the foot is pressed well upwards. If the patient be a young person, the cork must be worn till he have done growing, and care should be taken never to bear the weight of the body on the foot without it; for when the construction of the arch of the foot is considered, it will easily be conceived how little pressure will soon displace the bones again, and stretch the ligaments.

In more confirmed cases, but still not sufficiently rigid to require the division of the tendons, more powerful pressure must be made by means of a firm pad made to press against the inside and under part of the arch. To do this, the patient must be confined to the bed or sofa.

Of the division of the tendons for the treatment of talipes valgus.—The tendons requiring to be divided in talipes valgus are, both the long and short peronei, and the extensor communis digitorum with the peroneus brevis. The two former tendons always require division; the latter, only in rigid cases. I am not sure, however, that the majority would not be always benefited by the

common extensor being divided: it frees the ankle joint, and allows of the anterior half of the foot being brought down, while the arch of it is pressed upwards: it *loosens* the bones, if I may use the word. The difficulty experienced in dividing the two peronei is, that the more anterior of the two—viz. the peroneus longus—most frequently rides over the margin of the fibula, and is found placed upon the bone, instead of behind it. In adults the tendon can be easily felt; but in infants, where the tendons are very small, and the child fat, it is by no means easy to do so. Where the tendon is found to be riding on the bone, as just described, it is to be divided by passing the sharp-pointed knife rather obliquely, and in a position more anterior, in fact over the bone instead of behind it: so much of the tendon as lies upon the bone may be divided, when the point of the knife is to be dipped a little deeper to include the other tendon, if it be not raised to a level sufficient to be included in the division of the first one. In infants or young children the same precaution is to be taken, only the operation becomes more difficult from the greater difficulty of defining the margin of the tendon. In adults the division of the tendon is evidenced by an audible snap, and a marked interspace remaining. In infants the yielding of the foot with a slight jerk is felt more by the assistant than by the operator, and no perceptible interspace between the ends of the tendons remains afterwards.

The extensor communis is easily divided, by passing the knife beneath the tendons at the bend of the ankle-joint, just before they split to diverge towards the toes; one stroke of the knife then generally divides them all at once. Were the knife passed lower down on the instep, it would have to be pushed a long way beneath the skin to include all the tendons. Compresses and a few turns of bandage to confine them are placed over the punctures, and a splint, padded, is applied in front and to the inside of the ankle-joint for a week, to allow the wound to heal.

Of the Mechanical Treatment of Talipes Equinus.

A thick oval pad must be placed along the inner and under part of the sole of the foot in a position to press the astragalus and navicular bones

upwards. While this is being done, the toes and outer edge of the foot must be brought downwards and inwards; in fact, in a direction as if an attempt were being made to produce *varus*. This object is gained by having the pad attached to a strong spring which extends to and beyond the great toe, and is curved from it; the other end of the spring is fixed to a splint of the width and length of the legs, along the inner edge of which it is placed, and extends as low as the ankle. This splint is well padded, and firmly fixed to the leg by means of bandages and straps. The foot is then to be fixed to the spring by pressing the latter towards the foot, and the pad, of course, with it against the arch; and then passing two or three straps round the toes and free end of the spring by means of small buttons on which the strap hooks. These straps are to be gradually tightened till the arch is returned to its proper shape.

The arch of the foot being redressed, it has to be supported, as I have already described, by means of the raised cork sole within the boot. If the ankle-joint be weak, or disposed to fall inwards, the boot must have an iron attached to it, extending from the sole up to the knee, being placed on the outer side, and standing some way off from the ankle, round which a broad strap passes, which supports the joint, and brings it outwards towards the iron.

Of the Treatment of Talipes Equinus Valgus.

Nature of the deformity—Eversion of the foot, flattening of the arch, and elevation of the heel or locking at right angles. It is more frequently non-congenital, and very often paralytic, the muscles on the anterior part of the leg having lost all power of flexing the ankle-joint. The extensors of the knee are also frequently paralysed at the same time, causing the patient to throw the leg out, having no control over it.

In the paralytic cases the only tendon requiring to be divided is the tendo-achillis, and the points to attend are to take great care that the uniting medium be not too quickly stretched, otherwise the tendon will be weakened to an extent that its power over the heel will be lost, and the os calcis will drop, converting the case into one of *talipes calcaneus*, and so leaving the patient worse off than before. A fortnight should be

allowed to elapse in these paralytic cases before extension be made upon the divided tendons, and then it must be done very gradually, indeed.

When the heel has been brought down, and the arch redressed, the same plan must be adopted with regard to the boot as just described: the joint, however, had better be supported by means of a double iron with a stop-joint, one on each side, and a very broad ankle-strap passed round the inside of the ankle, and round the outer iron. If the knee be paralysed or weak, the iron should pass above the knee, and have a support behind the joint as well. In young children it is a very good plan to have the whole limb fitted into a leather case, closely surrounding the thigh and upper half of the leg, fastened by straps and buckles. The iron in the boot is also attached to it, and fixes the ankle joint in the same way as before.

In the non-paralytic cases there is, of course, no occasion for the iron to extend above the knee, and there must be a strong lock at the ankle-joint of the iron to prevent the heel being brought beyond the right angle.

Of the Treatment of Talipes Calcaneus.

Nature of the deformity.—It may be congenital or non-congenital; if the former, I believe it depends upon position "in utero," although the muscles in the anterior part of the joint may appear to be more rigidly contracted than natural. I believe they have only become so by having accommodated themselves during their growth to the position of the foot. There is no paralysis of the muscles connected with the tendo-achillis in these congenital cases.

In the non-congenital cases there is always paralysis, causing the heel to drop; and in extreme cases, so much so, that the os calcis is almost brought into a straight line downwards with the bones of the leg. The plantar fascia in most of these paralytic cases is contracted to an extreme degree, causing the arch of the foot to be apparently increased by the hollow that exists beneath it. It will be found, however, to be principally caused by the dropping of the os calcis, and its approximation to the toes; for the plantar fascia having lost all resistance to keep it on the stretch, by the loss of power in the tendo-achillis to pull it backwards, remains in its original shortened condi-

tion if the attack have commenced when the child was young, and the bones small, and does not grow with the rest of the foot.

In congenital cases of *talipes calcaneus*, if very rigid or unyielding, the extensor communis digitorum must be divided by passing the point of a small knife beneath it, just at the bend of the ankle, and extension be made after four or five days by placing a small padded tin splint on the anterior part of the leg and instep, and so gradually bringing the foot down to its natural position.

The non-congenital cases of *talipes calcaneus* constitute one of the most unsatisfactory class of deformities the surgeon has to treat; there is, perhaps, only one more so—namely, the *calcaneo valgus*; for the principal cause of the deformity being the loss of power from complete paralysis of the large and powerful muscles of the calf of the leg, which generally become so much atrophied as to preclude all chance of recovery, leaves the foot in a much more helpless condition than in the other kinds of deformities I have hitherto described. I believe all that can be done is, to endeavour to get the heel into better position, in those cases where it points vertically downwards, by dividing the plantar fascia freely, and then applying pressure on the instep in such a manner that the os calcis may be pushed upwards and backwards. I should recommend the division of the deep muscles, if necessary, at their point of attachment to the os calcis; for they may, in cases of long standing, take part also in opposing the replacement of the os calcis: partial improvement may generally be gained, but not complete.

As soon as the os calcis has been brought into position as much as circumstances will admit of, means have to be taken to fix the foot in such a manner that it may be kept flat upon the ground when the patient walks; and this can only be done by means of a double iron attached to the boot, with a "lock" at the ankle joint placed on the anterior part of the hinge, so as to prevent the heel from falling downwards; a broad ankle strap should also pass round the inner ankle and outer iron, as there is always a tendency to valgus in these cases, if it be not decided. The boot should also be made of good length, and fit the instep well, so as to press the heel firmly downwards and backwards.

by these means the patient may be made to walk better, and with comparative comfort.

Of the Treatment of Talipes Calcaneovalgus.

Nature of the deformity.—Dropping of the heel, and eversion of the foot, the most unsatisfactory of all deformities of the feet to treat. In most of the cases there may be said to be paralysis of all the muscles of the lower extremity below the hip, accompanied with extreme atrophy of the whole limb. All that can be done (and which is rarely required) in the way of operation is the division of the plantar fascia, to enable the heel to be brought more into the horizontal position.

The mechanical treatment required for these cases is to confine the whole limb, either by means of an iron extending the whole length, from the foot up to the hip, with proper straps and knee caps, or else place the whole limb in a case of thick leather, with irons attached to the boot. The iron must be double below the knee in both cases, and have a broad ankle strap passed round the outer iron to keep the ankle joint from falling inwards. In these cases the flexors and extensors of the hip are seldom, if ever, paralysed, so that the patient is enabled to bear his weight upon the limb when the knee and ankle-joint are artificially fixed, and walks with the aid of the hip-joint only.

In my next paper I shall consider some of the more practical points connected with contractions of the larger joints.

[To be continued.]

EXPENSES OF CHOLERA IN IRELAND IN 1849-50.

THE entire number of persons attacked with cholera in Ireland was 55,141. Of these no fewer than 8309, or more than one-seventh, were Dublin patients. There were in the

North Union	3787
South Union	4522
Total in Dublin	8309

The expenditure created by this visitation was altogether £41,102, of which the Dublin portion was only £2561, or about a twelfth.

PULMONARY DISEASES IN TROPICAL CLIMATES.

AND THEIR TREATMENT.

BY R. H. A. HUNTER, M.D., Surgeon.

Pulmonary diseases.—The next subject we shall glance at will be the class of pulmonary diseases; not because of their superior importance; but because they have been little noticed in works on tropical diseases, though certainly they are neither deficient in variety nor interest. Consumption, as we have elsewhere shown (*Transactions of the Bombay Medical and Physical Society*, No. 4), is a disease of moist exposed localities, without reference either to latitude, temperature, or elevation; and so occurs equally in tropical as in temperate climates. Thus it is found at its minimum in the dry sheltered climates of the East Indies, whilst in the West India Islands it attains nearly to its maximum. From inattention to this, very grave mistakes have been committed. Persons have frequently been sent to the West Indies on account of consumption, though this is about as reasonable (according to the above views at least) as to send those with chronic rheumatism or pleurisy to the frozen regions. It is sometimes objected, it is true, that Madeira is a good climate for the consumptive, but Madeira is not within the range of the trade winds, neither is it in "the variables," as they are called, but between these in the mildest region of the world. Madeira, too, is at no great distance (to the eastward) from the dry burning deserts of Africa, whilst from the west it is completely sheltered by the mountains; only the lower south-eastern face of the island being inhabited, by invalids at least; whereas the West India islands are far in the strength of "the trades," after these have swept nearly across the whole western ocean. So true it is, with respect to this disease at least,—*"Nam fere ventus ubique, a Mediterraneis regionibus veniens salubris—a mari, gravis est."* In the West India islands the ratio of mortality from consumption is certainly not less than one per cent, whereas in central India it is scarcely two-tenths. Neither can it be

always prudent to send the consumptive even to the southern shores of England, except the summer be decidedly dry; or perhaps, after all, some of the low inland districts might be a better locality, as Clifton or Bath. Indeed, it is to the sheltered localities of these last, rather than to the waters, we would ascribe their salubrity.

But the best place for the consumptive we know, and now within the reach of the wealthy at least, in thirty-five days, is Poona, under the Presidency of Bombay, as it also possesses the advantage of being as healthy as England in most other respects. Madras, too, is a good climate for the consumptive, and Bangalore (another excellent climate); but Bombay, Cannanore, and the Malabar coast generally, had better be avoided, at all events in the rainy season. In Bombay, indeed, one way and another, we met with more of consumption than in all the rest of India put together twice over.* It is there particularly frequent, too, among the "half castes," and those of European extraction generally, who have been brought up in India, insomuch that on our losing one of this class in the female (regimental) hospital, the late Archdeacon Jefferies mentioned he had never known one of the girls brought up in the Bycullah Orphan School reach the age of thirty, and chiefly from this cause. The regiments or detachments from the interior, also, soon lose their consumptive cases in Bombay, whether arriving as invalids or in the ordinary way of relief, and the same at Cannanore, and particularly during the moist stormy winds of the south-west monsoon.

If consumption be confirmed, however, any change only adds to the discomfort, and may hasten the event: nor would it be advisable to go to India otherwise than *viâ* Egypt, which is itself, I should say, a good climate for the consumptive about Cairo, not Alexandria, though, it is true, we have the authority of Celsus, that the latter is preferable to Italy—"ideoque aptissime Alexandriam ex Italia itur"—(I have myself only been once through this way). Many have the disease first set a-going during the voyage by the way of the Cape of Good Hope,† and it

is equally pernicious from the opposite direction. On one occasion, with invalids, we lost all our consumptive cases (three) between Bombay and the Cape, though none of them were supposed, previously to embarkation, to have been in a hopeless state. In fact, they were all embarked under other diseases.

Bronchitis.—This is another by no means infrequent disease in tropical climates, and, though seldom fatal, has in the higher localities in the East Indies a great tendency to run into a chronic or asthmatic form. From Poona particularly, to the east of the Great Western Ghats, we had to invalid several on this account, but in the low countries or coast have never known it have this termination. On the contrary, those from the interior have been immediately relieved, and many of them rendered fit again for service, in the low countries at least. Bronchitis also occasionally complicates the fevers in India, imparting to them a typhoid character, and adding greatly to the danger. Also in the West Indies; but here bronchitis, instead of assuming the asthmatic form, tends rather to consumption, becoming localized in one or other of the subclavian regions. It is to this may be attributed the mistake Colonel Tulloch has fallen into with respect to the frequency and mortality from pneumonia in the West Indies: this we sufficiently proved by a careful perusal of the records on the spot.

Hæmoptysis.—In the East Indies this occurs far more frequently than can be accounted for on the presumption of some latent tuberculous disease. Besides, it is more generally found to proceed from one or other of the lower lobes; but so seldom do such cases even eventually prove fatal in India, that it is difficult to say, perhaps, what their true nature is. We except, of course, those connected with phthisis, aneurism, or with disease of the heart. One we remember, however, in the lower left lobe, which, after two or three attacks, proved fatal, with all the symptoms of phthisis. In this there was a large regular cavity resembling the empty cyst of an abscess, without any other marked pulmonary disease. And another ultimately died away from head-quarters, who had been frequently under treatment for some years previously. Per-

* See a few cases, &c., "Bombay Transactions (Medical and Physiological)," No. 1.

† There are two rainy seasons, or zones, passed through this way.

haps there are two varieties, the one nearly allied to the first stage of pneumonia, which is immediately relieved by the hæmorrhage, the other to pulmonary apoplexy. In three cases of sudden death we found the pleura burst up, and the left cavity of the chest filled with blood. One of these, however, was originally a case of acute bronchitis, which as a pneumonia had been treated on the "heroic principle." Getting up in the night, he fell dead very unexpectedly, when on examination it was found the blood had escaped from a superficial gangrenous spot, at the bottom of the sulcus, between the two lobes. The gangrene was inferred chiefly from the colour of the membrane, but it was very limited, and in depth could not have exceeded a quarter of an inch. The two pleural surfaces between the lobes were partially adhering by very recent lymph, and the lower lobe was engorged with frothy serum. In the West Indies, also, hæmoptysis is frequent and copious: so copious, indeed, that in two cases we met with of phthisis it more resembled a pulmonary apoplexy. One of these, which had been in hospital for some months previously, without any alarming symptoms, proved fatal fifteen days after. The right lung was engorged with blood, as well as thickly studded throughout with large white tubercles, only a few of which had become softened. The other was a similar case, but he left with his regiment (19th Foot) in the hope that a sea voyage might prove beneficial.

There was a curious case we might notice here, which occurred at Poona in 1835, though not immediately connected with the above. It was that of a fistulous scrofulous abscess in the left axilla. The subject of it was a recruit, or at least recently arrived from England, of a rather gross habit of body. During the visit one morning, the discharge having ceased, he was suddenly seized with the greatest alarm and fear of impending dissolution. "*My breath is stopped!*" Nor was the least murmur audible on that side by the stethoscope, though the resonance remained perfect. The sensation and signs were exactly as if something had fallen into the left bronchus. Warm fomentations were applied to the axilla, under the impression some revulsion had taken place (there seemed to be scarcely time to

think), and as soon as the discharge returned, which was almost immediately, he was relieved. He had a similar attack some days afterwards, but eventually recovered, and for several years was an effective soldier; nor do I remember what became of him. I may here state, that regiment (the 2d, or Queen's Royal) numbered 854, exclusive of officers, on the day I joined Headquarters in Colaba, Bombay, and when I left them at Deesa, about twelve years after, not fifty of these remained.

Treatment.—On this subject a very few words will suffice. As regards consumption, indeed, not many cases comparatively, we have seen, last over six months. In bronchitis, however, we have been particularly fortunate, and not only so in the East and West Indies, but also in England; attributable, as we suppose, in a great measure at least, to the "*nonnima diligentia*." The pernicious effects of the too common routine of active treatment, we have witnessed certainly in many diseases, and if we except occasionally where there was no disease at all, in none more conspicuously than in bronchitis. A moderate venesection may be beneficial in many cases at the commencement, and cupping in moderation in the course of the disease; but time is the grand remedy; to gain time if possible, without exhausting the vital powers, and of all things to be sparing of blood. Bronchitis tends to death by suffocation or by apoplexy, not to any morbid alteration of structure incompatible with life, like pneumonia, hepatitis, or dysentery; to recovery, by a bland secretion from the air tubes, the work of time only; for though you may bleed to death, you cannot resolve the disease till then. After a moderate venesection perhaps, in recent cases, we exhibit an emetic of ipecacuan, adding a little of the tartarized antimony, and afterwards give the ipecacuan in smaller doses, with calomel or hydrargyrum cum creta (say gr. v. of each) alternately, every two hours or so, with some saline diaphoretic, to which is added either the vinum ipecacuanhæ vel antimonii. Whenever the breathing becomes much oppressed, we prefer trusting to stimulating pediluvia, mustard poultices or blisters to the chest, and say pulv. ipecac. gr. xx., whether it may act as an emetic or not. Nor would we be *busy* with the lancet or cupping-glasses, except dry cupping

perhaps, even under the most unfavorable appearances. (We remember a case of this kind some years ago, where these means were very strongly urged. The reply, however, was, "Never fear, he will be diligent in the morning" and sure enough in the morning it was his answer to the letter, "I'm illigant, I"). Afterwards, when the secretion is becoming copious and loose, or in the more chronic stages, the carbonate of ammonia, with myrrh, bitters with tinct. colchici, quinine, &c. &c.

In some old chronic cases we tried the pil. hyd. tart. ant., and ext. conii, as mentioned in one of the numbers of the *Medical Gazette* of 1842, or beginning of 1843 (our constant moving about prevents us carrying many books with us); but, like other remedies, we found it scotched, did not cure, for the cases soon returned upon our hands.

Many become extremely liable to this disease on any exposure to cold; often, indeed, without any assignable cause. In such cases, only change of climate is to be depended upon: and here Celsus's suggestion would be more appropriate perhaps—"Sic ut densius quam id est, ex quo discedit, aeger," though cold salt water sponging may reduce the susceptibility.

In hæmoptysis, unconnected with phthisis, moderate venesection and cupping, calomel, antimony, and opium, and a succession of small blisters; but the cure is seldom perfect, in the hæmoptote engorgements at least, or permanent, or the normal respiration restored.

Bristol, 8th August, 1850.

ARTESIAN SALT SPRING.

ACCORDING to Dr. Granville, a new Artesian salt-spring has just been opened at Kissingen, in Bavaria. The well is 1878 feet in depth; and the water, at the rate of 100 cubic feet per minute, is projected to the height of 52 feet above the surface. Its temperature is 66°; and it is said to contain 8.25 per cent. of pure chloride of sodium separable by evaporation. It issues from a bed of rock-salt, which has been penetrated to the depth of 138 feet. The rock-salt stratum is supposed to be 1000 feet in thickness.

MEDICAL GAZETTE.

FRIDAY, AUGUST 30, 1850.

WE beg to direct the attention of our readers to the report of another trial for manslaughter by poisoning with *Lobelia inflata*. The northern counties have within the last few years acquired a disgraceful notoriety from the numerous cases of poisoning by lobelia which have occurred in that part of England: and, if we are to judge from the verdict in the case which we now report, it appears highly probable that this benevolent method of destroying one's neighbour will continue henceforth unchecked. A trial by jury for such a crime, in a county in which the lobelia quackery is so extensively diffused that even a verdict of *Not guilty* is received in open court with a "murmur of satisfaction," is surely a mockery. Justice cannot be done. It is time that the *venue* should be changed,—in other words, that a jury should be selected from a county not yet infected with this form of vegetable quackery. For our part, we do not see why the Attorney-General should not, on every future charge of this kind in Cumberland, exercise the power of entering at once a *nolle prosequi*.

The facts are much the same in all the cases.—A friend, with good intentions, administers an active poison without having any experience of its properties, dose, or uses. He gives an *ad libitum* quantity to a fellow-workman just as ignorant as himself, and both have a dreamy idea that the vegetable poison is a "cure for all diseases," that you cannot take too much of it, and the more violently it operates "upwards or downwards" the stronger is the proof that a sufficient quantity has not been taken. If the man dies, it is quite certain that the drug could not have killed him; but that a fit of indigestion or

spasm, for which lobelia is the very best remedy, must have carried him off! There is another curious feature in these cases; this is, that they are sure to meet with a defender in Mr. Sergeant Wilkins. The learned counsel appears to be the Attorney-General of the disciples of Mr. Coffin; and it would be as great a phenomenon to find a Cumberland jury returning a verdict of *Guilty* as it would be to find a case in which Mr. Sergeant Wilkins was not retained for the defence.

Our readers will perceive, from a report of this trial elsewhere inserted,* that there were two simple questions for the jury to decide—1. Did the deceased die from the effects of lobelia? 2. Was it administered ignorantly and unskillfully by the prisoner?

The counsel for the defence, and the learned judge himself, who is described as having been favourably impressed towards the prisoner, made a great point of the admission that there was no imputation on the prisoner's "motives." If this means anything, it is that the prisoner did not wilfully administer the poisonous drug; and the answer to a suggestion of this kind, which an ignorant jury were likely to interpret as a very favourable circumstance to the prisoner, is, that had there been any imputation on the prisoner's "motives," he would probably have been arraigned on a charge of murder, and not of manslaughter. The good-natured judge and the cunning counsel, therefore, concurred in placing before the jury a fact likely to influence their verdict, although, strictly speaking, it had no thing to do with the charge. Manslaughter by poison presumes an absence of criminal motive.

A kind-hearted friend may administer to a person an ounce of bitter-almond water for the purpose of allaying spasms. He may have heard that it will do good

—have administered it, with this view, and his feelings may have been "of the very best and most friendly kind;" but still his friend may die; and the legal question, as we understand it, for making out a charge of manslaughter, is whether death was really caused by the ignorant and unskillful administration of the drug, not whether the man had a good or bad motive in administering it. This principle, would operate on the amount of punishment, not on the nature of the crime. These kind-hearted and good-natured friends, who persist in gratuitously poisoning you out of sheer benevolence, should be taught that if they will prescribe drugs, of the doses and properties of which they know nothing, they must incur the chance of a conviction for manslaughter. This trial for poisoning by lobelia shows us that the death of a fellow-creature, although unquestionably proved to be the result of ignorance and unskillfulness, is not treated as manslaughter by a Cumberland jury; and their verdict of *Not guilty* gives rise to "a murmur of satisfaction" in Court.

We for the present pass over the sophistry and complete ignorance of medical science, rendered all the worse by the assumption of knowledge, displayed in the defence. Our business is to consider whether there was evidence to show that the man did or did not die from the effects of lobelia. The prisoner admitted the administration of the drug, and this was also admitted by his counsel; although the latter took such liberties with the common sense of the jury, as to assert that the green vegetable matter found in the stomach, with *signs of irritation beneath it*, might have been potatoes, greens, or onions, which it does not appear that the prisoner prescribed or the deceased swallowed. The prisoner's counsel disputed Mr. Wilson's evidence respecting the presence of lobelia in the body of the deceased; and while he at one time complained of

the non-production of the vegetable powder found in the stomach, he at another time admitted "that the administration of lobelia was the very best thing that could be done for the deceased," as it would by its emetic properties have the effect of removing from the stomach the putrescent vegetable matter lodged there, and, being antispasmodic, it would cure the spasms!

The quantity of lobelia administered by the prisoner is unknown. The evidence shows that the deceased took two doses from a basin on the Wednesday evening; and it is highly probable that the "dark mixture" sent by the prisoner on Thursday contained the same drug. It is not pretended that the officious friend prescribed anything but lobelia in the treatment of the deceased. Previously to taking the mixture on Wednesday evening at ten o'clock, with the exception of slight heartburn, we learn that he had been in good health. Soon after taking the mixture, he was seized with violent vomiting, which continued throughout his illness, if we except a short remission on Thursday afternoon. The vomited matter is described as of a green or lightish green colour. Death took place in forty-four hours. The stomach and intestines were found inflamed; and, *covering the inflamed parts*, was a quantity of green vegetable matter, recognised by smell and other properties to be identical with powdered lobelia—the substance which prisoner admitted he had given to the deceased on Wednesday evening, shortly before the violent and fatal illness commenced.

The deceased appears to have sunk under the incessant vomiting and the exhaustion thereby produced, as well as from the specific action of the poison. There was no morbid appearance of any kind, irrespective of that caused by the vegetable irritant, to account for the incessant vomiting; and there was certainly no disease of the stomach to ac-

count for it. It is, therefore, we think, incontrovertibly proved by the general and medical evidence, that the deceased did die from the effects of lobelia. There was no other cause in the body to account for death.

The other question is—Was the drug administered *ignorantly and unskilfully*? The prisoner was a foundryman,—had no experience in medicine or knowledge of drugs. He had probably heard of the good effects alleged by a certain class of quacks to be produced by lobelia, and without any knowledge of the properties, or mode of action of this medicine, he gave evidently a very large and poisonous dose to the deceased, probably with the intention of benefiting him. We say that the dose must have been very large; for, without entering into the question of how many doses had been given during the deceased's illness, the mixture of the powder in a basin by the prisoner, the fact that the deceased vomited a greenish-coloured matter for forty hours, and that some of the vegetable powder was afterwards found in the stomach and bowels on inspection, are abundant medical proofs that a large and poisonous quantity of the drug had been taken in one or more doses by the deceased during the forty-eight hours which his illness lasted. These facts clearly establish, medically speaking, that an active medicine must have been administered in a poisonous dose with ignorance and unskilfulness, but probably with the very best and most friendly intentions. If these facts do not establish *ignorance or unskilfulness*, what are the proofs which the law requires? On the other hand, if in this case the verdict were proper, and the murmur of satisfaction with which it was received justifiable, it follows either that the deceased did not die from the effects of lobelia, or that his death was an accidental result of its scientific and skilful administration!

There is an old saying, and a very just one—*Judex damnatur cum nocens absolvitur*; and we are inclined to regard the acquittal in this case as a result of the imperfect charge on the part of the judge.

The speech of Mr. Sergeant Wilkins, embracing the wildest and most untenable propositions in medicine, was allowed to have its influence with an ignorant jury. The learned Sergeant, who is a sort of renegade from the profession, invariably commences, what the newspapers call his "energetic" defence, with an attack on medical men and medical science. When practitioners are dragged into a Court of Law in these cases to give evidence for small fees, and under a serious loss of practice, the learned Sergeant charitably assumes that the *only* motive which actuates them, is one of persecution arising from the interference of unlicensed persons with their profits or their prejudices! Because a blacksmith in Germany (Priessnitz) had introduced hydropathy, *therefore* the Cumberland people were to poison each other with lobelia! He was told by all the medical witnesses that *they* had not employed lobelia, and did not employ it, because they considered it unsafe as a medicine, and because there were other remedies at hand which were safer and more effectual. They had not tried his client's experiments with the drug,—i. e., of giving it in large and poisonous doses from a basin, and therefore they knew nothing about it! "An attempt was made to convict the prisoner of felony on the evidence of men who knew no more about lobelia than any one of the jury." The learned Sergeant therefore thinks that the only medical witness whose evidence will be worth listening to at a trial of this kind, is a practitioner who has incurred the risk of transportation by faintly poisoning half a dozen of his patients with lobelia. No experience short of this will satisfy him. Lobelia

is largely used in America, but only by quacks in dangerous doses: yet "why," said the learned Counsel, "did they not hear of its being productive of mischief?" This would be a fair question, if the learned Sergeant and the Cumberland jury were of the medical profession, and in the habit of perusing weekly the American medical and other journals; but as this is not the case, we do not see that the occurrence of mischief from the use of this drug is disproved, merely because the learned Counsel and the jury have not heard of the fatal cases.

The attempt of Mr. Sergeant Wilkins to account for the death of the deceased from natural causes, is a very fair specimen of the mode in which the facts of medical science are sometimes allowed to be abused and perverted in a Court of Law. Six weeks before swallowing the fatal dose of lobelia, the man had cramp, the result of wind and flatulency: this, it was argued, arose from *impure* gases evolved as a result of fermentation and indigestion. Hence it was inferred that the food in this man's stomach became decomposed and putrescent, and accounted for his sudden death! As persons had died from the effects of constipation produced by overloading the stomach, so it was contended the facts in this case were such as to induce the jury to believe that this man had died from a similar cause! The symptoms were then referred to the sour beer, although they had actually commenced twenty-four hours before any beer was swallowed, and continued to be of the same character throughout the illness. The learned Counsel contended that if the drug produced the vomiting described in the evidence, none ought to have been left in the stomach. This was a question of fact; and although the statement of Counsel is quite opposed to medical experience, it was allowed by the judge to go to the

as an unquestioned truth! The last medical hypothesis broached by the learned Sergeant was to the effect that the absence of purging might have produced all the symptoms seen, i. e. the incessant vomiting of 'green matter' and the patches of inflammation found in the stomach and bowels after death!

This is only a faint abstract of a few of the points urged in defence by the learned Counsel for the prisoner. Our readers, will, we are sure, agree with us that if he had assigned the death of the man to poisonous fungi suddenly generated in the stomach by fermentation, he would have been quite as near to the truth, and would thus have been able to explain in a few words, to the satisfaction of the jury, the cause of the green colour of the vomited matter, as well as the nature of the vegetable powder found in the stomach after death!

As to the charge of the learned judge, we regret to have to express our opinion; that if the report be correct, it could not in any way assist the jury through the mass of medical ignorance and sophistry which had been placed before them in the defence. Thus they were told that the prisoner's feelings towards the deceased were of a "friendly" kind. There was then a dry exposition of the law: they were requested to satisfy themselves that the deceased had died from lobelia, but how, or in what way, they were to become thus satisfied, the learned judge altogether neglected to point out to them. The man died either from lobelia, or from some one of the numerous causes suggested by the counsel for the defence—i. e. flatulency of six weeks' standing, indigestion, fermentation, or constipation of two days' standing! Not the slightest attempt was made to show how the medical evidence disproved these absurdly assigned causes of death. The jury were left to make a conjecture. They were told

that lobelia was not much known in England; that when administered in large doses, and under improper circumstances, the effects were such as many persons were unable to endure.* Even this good-natured way of speaking of lobelia as poison, and as a dangerous and unsafe medicine, was entirely neutralized by the additional remark, that "many drugs, even in the most common use, were, when given in large doses, and under improper circumstances, most deadly poisons." The jury were thus led to associate lobelia with colocynth or rhubarb: and this pharmaceutical association with the "flatulent" theory of Mr Sergeant Wilkins still ringing in their ears, will fully account for the verdict of acquittal, and the murmur of satisfaction heard in Court.

We must express our astonishment that a member of the judicial bench should, with such evidence before him, have left it to the jury whether the deceased died from *indigestion*, or the effects of lobelia! There was not one particle of medical evidence to show that indigestion was even a probable cause of death. Neither the symptoms nor appearances in the body could admit of any explanation on such an hypothesis. It was a mere random suggestion, thrown out by the prisoner's counsel, and adopted as probable by the learned judge, although the medical facts of the case were altogether opposed to it.

When all had thus terminated in favour of the lobelia quackery, the learned judge remarked, "It was to be hoped that all parties of insufficient education and skill would for the future be cautious how they dealt with such drugs as this." Either the verdict was

* This is a truism of wonderful force. It is only equalled by that attributed to M. Boyer, in which he sternly declared his conviction that "to die is a religious duty which every human being owes to his Creator."

ntrue, or such advice on the part of the judge was wholly misplaced. The jury, by their verdict, did not admit that there was *insufficient education and skill* on the part of the prisoner; and any one acting like him as a prescriber of lobelia in Cumberland, needs not to attend to the grave caution of the Bench; for the jury must have thought that it had only those qualities possessed by drugs in common use, or they would not have acquitted the prisoner. Their verdict plainly implies that it requires no medical skill or knowledge to prescribe: any blacksmith or pedlar may safely take up this line of practice; and if a person happens to die after having swallowed a large dose, all that is required is to refer his death to fermentation, or to some form of indigestion!

Trials so conducted appear to us to be a mockery of justice. It would be a great saving of unnecessary expense if the County in any future case declined to prosecute; and after the imputation of improper motives, which, without any censure or remark from the judicial Bench, was thus allowed to be unjustly cast on members of the medical profession, we think it would be only fair if the Cumberland practitioners permitted these "lobelia poisonings" to continue unchecked. In the course of time the fatal cases of "indigestion" would become so numerous as to excite the suspicion of Government, and thus lead to the adoption of some better means of repressing the crime of poisoning by the ignorant and unskilful use of noxious drugs, than appear to be now available in the criminal law.*

* The subjoined case furnishes an additional example of the good-natured way in which these friendly instances of poisoning are disposed of. It was tried in the Crown Court at Liverpool, on the 30th inst. by the learned judge who tried the lobelia case.

"CROWN COURT.—(Before Mr. Justice WIGHTMAN.)

"Robert Lees was charged with the manslaughter of an infant named Elizabeth Corrie, by negligently and unskilfully administering to her an over dose of laudanum.

"It appeared that on Sunday, the 4th of August

The Diseases of the Breast, and their Treatment. By JOHN BIRKETT, F.R.C.S.E., Assistant Surgeon to Guy's Hospital, 8vo. pp. 264. London: Longman and Co. 1850.

THE Jacksonian Prize for the year 1848 was awarded by the Council of the College of Surgeons to Mr. Birkett's essay on Diseases of the Breast. That the award was just, and the essay in every respect worthy the distinction, its reproduction in the present treatise will sufficiently attest. Every known form of disease to which the breast is obnoxious is here accurately described under all its varied aspects and conditions, its history, symptoms, progress, treatment, and termination. The con-

last, the wife of John Corrie went with another woman to a public-house in Dale Street for a glass of ale, carrying with her her infant, which was seven months old. There she saw the prisoner, who observed to her that her child was not well. She said it had been suffering for some days from a bowel complaint; and the prisoner then said he would give her a prescription for the child which would relieve it, if she liked. She assented to this, and the prisoner dictated a prescription, which a young woman present wrote down. '3 oz. of chalk mixture, 1 oz. of gum arabic, and 2 drachms of laudanum: two tea-spoonful to be given as a dose.' This Mrs. Corrie got made up at a druggist's shop, and administered one dose to the child, which, according to the evidence of the medical witnesses, would contain 14 drops of laudanum. The result was that the child became drowsy, and died eight days afterwards. In the opinion of the surgeon who made a post-mortem examination of the child, it had died from the effects of a narcotic poison.

"The prisoner, in defence, alleged that he had never told Mrs. Corrie to put laudanum in the prescription, but 'rhea'; that he had no intention to injure the child; and that he had dispensed medicine for twelve years, and had never committed a mistake.

"His LORDSHIP, in summing up, said the prisoner appeared only to have acted from motives of kindness; but if they were of opinion that he had acted with negligence, want of skill, presumption, and ignorance, they ought to find him guilty. The child had also died at a longer than the ordinary period after the administration of a narcotic poison; and it was therefore for them to consider whether or no the dose administered had caused its death.

"The jury found the prisoner Not Guilty."

This case adds to the difficulty of comprehending what can be legally intended by the unskilful and ignorant administration of powerful medicines. If the accused had prescribed two drachms of Scheele's prussic acid instead of tincture of opium, we presume that, as he had only acted from motives of kindness, there would have been no ignorance or unskilfulness, and that he would have been equally discharged of all legal responsibility for the death!

sideration of these is preceded by a short anatomical description of the healthy gland, and a copious bibliography.

The diseases of the breast are arranged under the following periods by the author.

"I.—*Before* PUBERTY.

"II.—*During* THE ESTABLISHMENT OF PUBERTY.

"III.—*After* THE ESTABLISHMENT OF PUBERTY.

"1. During pregnancy, the puerperal period, and lactation.

"2. At any period or age after puberty."

Few diseases of any importance occur to the breast during the first or second periods; but the author recites from the Medical and Physical Journal an interesting case, of unprecedented extent, of inflammation of the breast, spreading to the whole anterior surface of the body, in an infant about a month old.

In the third period, or that of adult female life, the number of diseases to which the breast is exposed necessarily becomes considerably augmented. Of these the most frequent is inflammation, *mazotitis* (a. Ma^gde), as it is termed by the author. This is divided by Mr. Birkett into,

A. Inflammation, and its results, in the cutis and subcutaneous tissues, covering,

1. The nipple; 2. The areola; 3. The gland.

B. Inflammation, and its results in the tissues behind the gland.

C. Inflammation, and its results in the tissues within the investing fibro-cellular envelope, or fascia of the gland:

1. Of the lobes or gland tissue; 2. Of the uniting tissue.

Mr. Birkett states that he is "quite prepared to deny the existence of true erectile tissue in the nipple." This organ consists, according to the author, almost entirely of yellow or contractile fibre, the advantage of which is, that it arrests the flow of milk when the ducts are distended with that secretion. This tissue exists almost alone at about a quarter of an inch from the apex of the nipple.

"When the nipple is placed in the infant's mouth, the warmth of this organ is sufficient to relax this contractile tissue, as we see in other parts, and the milk readily escapes. Again, that condition of the nipple in which it is said to be in a state

of erection is nothing more than either a peculiar contracted condition of this fibrous tissue, or the result of distension of the lactiferous tubes."

This statement, it appears to us, is not entirely consistent with the following.

"But when the infant is not at the breast, then, by the contractile power of this fibrous tissue, the nipple is retracted, and resumes its quiescent state." (p. 35.)

It seems to involve a contradiction, that the same tissue should be the means both of the erect and of the quiescent state of the same organ. At the same time that the author denies the existence of erectile tissue in the nipple, he admits what is virtually the fact of erection, when he says that

"to enable the infant to suck with facility, the nipple must be elongated; and this condition is effected by the distended state of the tubes." (p. 35.)

To our apprehension, this temporary distension is as veritable an erection as if it had been caused by a flow of blood to special vessels. That Mr. Birkett's view of the cause of what we should still be disposed to regard as an erect state of the nipple—viz., the distension of the lactiferous tubes, is correct, is confirmed by the fact which we have noticed to obtain generally, that where the nipple is defective, there is also a deficient supply or total absence of the secretion of milk.

The remaining forms of inflammation in the breast, the acute and chronic abscess, are all forms of disease with which most practitioners are conversant.

Diseases depending upon the development of cysts and intra-cystic growths come next in order: of these new growths the author observes, various writers have offered explanations, although none have entered very minutely into their organization. They are arranged by Mr. Birkett as follows:—

I. Cysts depending upon dilatation and a morbid condition of the lactiferous ducts or acini.

II. Cysts produced by a peculiar action in the fibro-cellular envelope of the gland-tissue, and the consequence of a morbid state of the function of nutrition.

The existence and formation of the first of these forms of disease are traced by the author with accuracy. The author at the same time explains them by reference to a diagram.

Mr. Birkett thus describes the formation of a disease of the fatger ducts near the nipple, presenting a cystiform character:—

"In the first place an excess of secretion takes place in the duct, which, from some cause or other—malformation of the nipple, or obstruction of the duct by pressure—does not flow away spontaneously, although perhaps it may be made to come out. The fluid becoming absorbed, the more solid material, the epithelium, remains behind, leaving a coherent mass of more or less solidity. This body may cause irritation; an excited action is induced, blastema is effused, and nucleated cells, which attain a degree of fibrillation, are formed: hence the appearance of organized growths found in the ducts." (p. 68.)

This form of disease may be extensively complicated, but remains distinct from carcinomatous disease, although the two may co-exist. The author also points out, with reference to these new growths and their contents, that we may find in them the traces of abnormal nutrition and secretion, and of an abnormal development of gland tissue, also of an arrest of development at certain stages through which we know that all perfectly-formed tissues have progressed. "It is important," as the author remarks, in the consideration of morbid actions, to determine clearly whether or not the morbid product be a disease *in* or *of* the tissue in which it is found.

We quote the author's conclusions in reference to these tumors:—

1. That certain collections of fluid take place in the areolar tissue of the mammary gland.

2. That a cyst or closed cavity is formed, and lined with tessellated or hexagonal epithelium.

3. That the physiological relations of this fluid may be regarded as differing from ordinary serum, and that it may be considered as superabundant effusion of blastema.

4. That the intracystic growths, being developed within the sphere of nutrition of the mammary gland, present more or less resemblance to the gland tissue, both to the unassisted eye as well as when examined with more minuteness.

5. That from the observations above made, these growths may be regarded as an imperfectly-developed gland tissue; and

6. That their tissue presents no resemblance to that of the carcinoma, and that there exists no evidence to prove that it has the power of contaminating other tissues, or of being generated in any other organ belonging to the body.

Hypertrophy of the mammae forms the subject next under consideration.

Under the head, "Diseases of innervation," the author treats of—

1. *Neurodynia*, or a painful affection of the organ generally.

2. *Lebular chronic induration* of the normal tissue.

3. *Lobular imperfect hypertrophy*: a new growth.

Among the various subjects which follow, we notice—Atrophy, Tubercle, Enchondroma, Osseous growths, Hydatids, &c. The diseases of Lactation, Morbid conditions of the Milk, Diseases of the gland in the male, and Carcinoma. Besides these, several other still rarer forms of disease, or morbid conditions of the gland, are noticed by the author. In short, as we have said, every known form of disease will be found to have received notice in this treatise, with all its varied aspects and conditions, its history, symptoms, course, and treatment. A selection of cases illustrates or proves the existence of each form of disease, and a number of well-executed coloured engravings also afford clear ideas of the diseases spoken of. The drawings have been executed by the author himself, and are drawn on stone by Messrs. Hurst and Tupper.

To say that this work stands alone, and forms the most complete treatise on the diseases of the Breast that has appeared since Sir A. Cooper's great work, is not saying too much, as every scientific practitioner who examines it will admit.

TEMPERATURE OF THE EARTH.

In the deepest mine in Ireland, according to Professor Oldham, the increase of temperature below the level of no variation amounted to only 1° for every 85 feet. The mine has been recently deepened from 800 to 1200 feet; but the results of new observations on the temperature are the same, although in another shaft, at a distance of only 800 yards, the increase is 1° for every 58 feet. In England, and on the Continent, the average increase of temperature is 1° for every 46 feet of depth.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Edinburgh; August 1.

Is Sulphite of Lead a Poison? Remarks on the Lead process for refining Sugar, and the probable danger arising from the use of Sugar thus refined.

In the Chemical Section of the British Association a question of some importance in relation to public health has been discussed: it is, whether *sulphite of lead* does or does not possess injurious effects by operating as a slow poison on the human system?

Dr. Scoffern read a paper on the *Sugar Produce of the South of Spain*, in which he stated that by the application of his patent process of refining sugar by the use of subacetate of lead, a considerable saving was effected in the amount of labour, in the cost of working, and in the more abundant produce from cane-juice of good crystallizable sugar.

It is stated that the salt of lead which the syrup may happen to dissolve in using the subacetate as a defecator, is separated by passing sulphurous acid gas into the syrup; so that, it is assumed, the whole of the surplus lead is converted to *sulphite of lead*, which is quite insoluble, and, as it is alleged, is entirely separated by filtration. An objection to this process is, that by some accident the whole of the lead may not be separated from the sugar, so that the crystallized loaf or the uncrystallized treacle might contain a small quantity, not of itself sufficient to do harm, except when the sugar or treacle has been used for a very long period of time. In this case, it is presumed, chronic or slow poisoning by lead may result, and be indicated by emaciation, loss of appetite, colic, paralysis, and other well-known effects caused by the slow and insidious introduction of the preparations of lead into the system. Dr. Scoffern, the patentee of this ingenious process, treats this as a groundless fear "which practice demonstrates to be entirely without foundation; for not only is the sulphite of lead most easily removed, but even were it to remain, no injury could supervene, inasmuch as this agent is as *harmless as chalk*." This involves a question of *fact*, and a question of *opinion*. The question of *fact* is, Does any lead, either as sulphite or in any other form, remain in the sugar or treacle as a result of

the new process? and the question of *opinion* is,—Is sulphite of lead—assuming this to be the form in which lead exists in the sugar or treacle—an inert substance, and as harmless as chalk?

On Wednesday, August 14, the subject was referred to in the House of Commons, and the Chancellor of the Exchequer then made the following brief statement.

"THE CHANCELLOR of the EXCHEQUER said that an inquiry had been made into the subject, it having been represented that by the process in question, a quantity of lead must remain in the sugar refined, and be productive, of course, of very deleterious effects. Three chemists of eminence had analysed the sugar so refined, and found that no lead remained in the sugar; but they were of opinion that considerable lead did remain in the treacle, the result of the refining. The inventor, however, who was supported by several chemists, disputed this opinion, and, as the best test he could give of his conviction to the contrary, offered that he and his family would eat any amount of treacle that might be reasonably proposed for their consumption. (A laugh.) However, the clearest way would be for the papers on the subject which he held in his hand to be laid before the House, and he would at once move that they be printed accordingly.—Ordered."

From the report of the analysis we entertain no doubt that the *fact* is settled in the affirmative,—that lead, as sulphite, or in some other form, remains in the sugar in small proportion, and in the treacle in comparatively large proportion, as prepared by this patent process. It matters not whether this has arisen from some imperfection in the process,—a bad filter, a filter breaking,—careless manipulation, or some other error in carrying out the advice of the patentee,—lead exists in the product. This fact rests upon an elaborate analysis made by Messrs. Graham, Thomson, and Hoffman, the three chemists referred to by the Chancellor of the Exchequer. Whatever caused the accidental introduction of lead in the specimens analysed by them, which are said to have been fairly taken, might, of course again operate at some future time; hence the public would never be with certainty secured against the purchase of sugar or treacle contaminated with lead. As a kind of answer to this view, it has been asserted that all varieties of sugar and treacle commonly sold contain more or less lead, owing to the employment of leaden vats or pipes, and iron cones painted with white lead, &c. This is confirmed by the results of the analyses of the three chemists above mentioned; but the quantity of lead found by them in sugar and treacle prepared by the ordinary

process was much less than in that prepared by the lead process. Still it would appear that all sugar is more or less poisoned with lead: and, if we understand the argument rightly, it is contended that the patent process is innocent because ordinary sugar contains lead, and we do not hear of any injurious consequences from its use. We are inclined, however, to place the question on this issue:—Ordinary sugar and treacle, like the patent sugar and treacle, either contain a noxious quantity of lead, or they do not. If ordinary sugar contains as much lead as the patent sugar, it is time for Government to interfere and prevent the use of lead in its manufacture; if it contains a much smaller, — i. e., an infinitesimal proportion, the argument is *inutil ad rem*; it then becomes a mere question of degree. At the same time, we know of no proportion of lead in any kind of sugar which can be said to be *innocuous*; it is in all cases a prejudicial impurity; and the discovery made by the chemists should therefore rather excite the Government to prevent its introduction into ordinary sugar, than to sanction its use on a still larger scale in the new manufacture of sugar. We have, however, heard it seriously contended that, because there is some portion of lead in common sugar, we ought to throw no obstacle in the way of employing the salts of this metal in the preparation of this universal article of food. Such an argument simply amounts to this. The English public are already poisoned to a certain extent by the accidental introduction of lead into sugar. Why should they object to be poisoned to the same, or, as it is alleged, to a greater extent, by the actual employment of the salts of lead in the sugar manufacture?

This, however, may appear to be begging the question, and here we fall back upon the matter of *opinion*:—Is sulphite of lead capable of acting as a slow poison, like carbonate of lead, or is it as harmless as chalk?

This was the question brought before the Chemical Section of the British Association. We take from the *Athenæum* report the following extract:—

Observations on the Sulphite of Lead. By
DR. GREGORY.

"Dr. Gregory stated that he had made experiments on the sulphite of lead formed in this process. He admitted that an infinitely small proportion might still remain in the sugar, but that he considered it quite innocuous. He had indeed fed rabbits and dogs with food which had been united with this sulphite of lead, and the result was that they thrived amazingly, showing no symptoms of any of the known effects of

lead. Dr. Gregory also remarked that, in testing sugar for lead with the hydro-sulphuret of ammonia, iron was often mistaken for the former metal.

Dr. CHRISTISON contended that we had no evidence that sulphite of lead was innocuous. It was true that in cases of poisoning by carbonate of lead sulphuric acid was administered to convert it into the comparatively insoluble sulphate; but this was a case widely different from the slow accumulation of lead in the system. Dr. CHRISTISON adduced some examples of exceedingly small doses of lead being taken in water for more than *twelve months* before its evil effects became apparent. He therefore thought it yet remained to be proved that the sulphite of lead was without action on the system, since we know nothing of the influence of the solvents it meets with in the system, or of the influences of vital action. Rabbits, he was prepared to say, should be entirely rejected in these inquiries, since he had found that they were not affected by many poisons. Dogs and cats were the only animals which could, from their internal structure, be regarded as the representatives of the human system in these investigations."

We must express our astonishment, that a man holding Dr. Gregory's position in the University of Edinburgh could treat such an important question as this, affecting as it does the health of millions, in such a loose and careless manner. Dr. Gregory is known as a chemist,—certainly not as a physiologist or a toxicologist,—and this is the only reasonable excuse we can find for the inconclusive nature of his experiments with the sulphite of lead. His chemical objection, or rather insinuation, against the results of the analysis of sugar,—namely, that iron may be mistaken for lead by the use of hydro-sulphuret of ammonia, cannot be considered applicable to the results of Messrs. Graham, Thomson, and Hoffman. They obtained the lead in the form of sulphate, and took those precautions which men of their experience and standing would unquestionably take, to prevent the occurrence of such a fallacy as that suggested by Dr. Gregory.

Dr. Gregory gives no explanation *why* he considers the sulphite of lead innocuous. As Dr. CHRISTISON very properly stated in reply, there is *no evidence* to support this view. The special effects of chronic lead-poisoning are undoubtedly traceable to the *oxide* of the metal, and not to the acid with which it happens to be combined. It is true that, like the sulphate of lead, the sulphite is insoluble in water; but insolubility in water cannot be received as any proof that a

substance exerts no poisonous action on the human body. Calomel and white precipitate are just as insoluble in water as sulphite of lead; and the same remark applies to Scheele's green and carbonate of lead: but it would be contrary to daily experience to assert that calomel, Scheele's green, and carbonate of lead, were therefore innocuous! The fact is, the human stomach, with its acid and mucous secretions, presents a solvent differing from water, and an absorbing surface of great extent and activity. The absorption of a mineral poison cannot, therefore, be regulated by the mere solvent action of water upon it. This is proved by the rapid absorption of powdered arsenic, and other mineral poisons not easily dissolved by water. There is no other reason, that we are aware of, for asserting that sulphite of lead is innocuous, than that derivable from the fact that we have had as yet no experience of its action on the human body.

The recent researches of M. Bernard* on the phenomena of absorption, show that substances insoluble in water are susceptible of absorption, and that the old doctrine—"corpora non agunt nisi soluta sint," is not founded on fact. Vermilion and Prussian blue, used in tattooing, have been detected in the neighbouring glands. It would be impossible to explain the action of a small dose of calomel on the liver, except on the supposition that it must become absorbed by the mucous membrane. Mercury has been found in the liver, and in all the soft organs of persons to whom calomel has been administered. How has this most insoluble substance been conveyed there, if not by absorption? Until experiments show the contrary, it is reasonable to assume that sulphite of lead is similarly absorbed. If absorbed, has it been proved that the sulphurous acid is so complete an antidote to the poisonous properties of oxide of lead, that the sulphite thus introduced into the circulation cannot act on the system like other salts containing oxide of lead? We do not find that Dr. Gregory has performed any experiments on the absorption or non-absorption of this substance, although such an inquiry was highly important before any inference was drawn by him respecting the innocuousness of the salt. The quantity absorbed might, it is true, be too small for detection, unless the administration had been continued for a very long period of time. If, however, lead had been detected in the tissues of the dogs and rabbits to which he gave the sulphite, he would have had great difficulty in persuading physiologists that the ab-

sorption of this substance might go on without in any way affecting health, or producing, after some months, the usual consequences of lead-poisoning.

It is very likely that a dessert-spoonful or a table-spoonful of sulphite of lead might be swallowed by an adult without acting as a poison or causing death; but this proves nothing with regard to the case under consideration. Carbonate of lead swallowed at once in a large dose is equally innocuous; but this substance taken day by day diffused in water, in the proportion of only from 1-60,000th to 1-100,000th part by weight, produces all the effects of chronic lead-poisoning. As Dr. Christison observes, it may take twelve months to produce these dangerous consequences, but in the end they will appear. How has Dr. Gregory met a case of this kind?—"He has fed rabbits and dogs with food which had been united with sulphite of lead, and the result was that they thrived amazingly, showing no symptoms of any of the known effects of lead." His conclusion, therefore, is, of course, that sugar containing sulphite of lead, as he says, in infinitely small proportion, though without giving any numerical results, may, with the treacle, be used by the public with the certainty that after any period of time they will not suffer from any of the effects of lead-poisoning!

Dr. Gregory's experiments, if they prove anything, have the unfortunate tendency to prove too much. He has actually discovered in the sulphate of lead a "chemical fattener." The animals fed with it not only showed no symptoms of lead-poisoning, but *throve amazingly!* The attention of the framers of poor-law dietaries might, therefore, according to this curious result, be profitably turned to this branch of industry. We can hold out no hope, however, that there will be any saving in the article of food by mixing it with sulphite of lead. The experiments are inconclusive and unsatisfactory. They throw no light upon the truth of the case, and have a direct tendency to mislead those who cannot perceive the numerous fallacies which they involve. It is not stated by Dr. Gregory how many dogs and rabbits were made the subjects of these experiments—what quantity of sulphite of lead was given at a dose—whether this sulphite of lead was or was not in the same impalpable state of division in which it exists in the patent sugar, or of suspension and probable intimate combination in which it exists in patent treacle—for how long a time the sulphite was given, and the nature of the food with which it was united. All these are facts required to test the correctness of conclusions which, if erroneous, may merely have

* L'Union Médicale, Septembre 1849.

the effect of spreading an epidemic colic throughout the British empire. We therefore quite agree with Dr. Christisen, that it yet remains to be proved that sulphite of lead is without action on the system; and the onus of proof lies with those who assert that it is innocuous, since *oxide of lead* is known to be poisonous, and there is nothing to show that its combination with sulphurous acid *renders it inert*. A few dogs, cats, and rabbits, are not the proper objects of experiment for solving a question upon which the health of a nation may depend. The actual effect produced by administering powdered carbonate of lead united with food to dogs and rabbits has not, so far as we know, been tried. It appears to us that, before drawing so sweeping a conclusion from the negative results obtained from sulphite of lead, Dr. Gregory should have tried the carbonate in the same doses and under the same circumstances, as a preliminary experiment. Negative results might have been here obtained, and in this case it would have been proved that the action of small doses of a known poison on animals is influenced by too many circumstances to allow of any fair comparison with their effects on man. It might have been shown that carbonate of lead given to these animals not only did not produce the known effects of lead, but that the animals while taking it thrived amazingly. In fact, it would probably have been thereby clearly established that carbonate of lead is quite *innocuous*; and that the accounts published of individuals suffering from drinking water containing only 1-70000th part of its weight of this salt, are fabulous tales.

It is assumed by Dr. Gregory that sulphite of lead is the only form of lead-salt contained in the patent products. In the treacle, as we infer from the report, it is mixed with acetate of lime, and is in an intimate state of combination. Dr. Gregory's sulphite, we presume, was prepared and given under widely different circumstances.

It has been stated that the patent sugar and treacle may be, and have been, taken with impunity for some time by adults and children without ill effects. This is possible; but still even such a result, if free from fallacy, does not exclude danger to the public in general by the use of an article of food which is liable, when well prepared, owing to unavoidable accidents, to contain a small quantity of lead, and when ill prepared to contain a dangerous quantity. How are the public to be guarded against a noxious impregnation, when the quantity of lead present, even under skilful hands, is liable to great variation? As to the negative results obtained from the consumption of

this patent sugar by ten or twelve persons for several months, they prove nothing conclusively. In the case of the ex-Royal Family of France, poisoned by the impregnation of the water of Claremont with lead, only 13 out of 30 persons suffered from the effects. This shows that not more than *one in three* may be affected by lead-poison in a given time—i. e., seven months. Had the 25 who escaped out of the 30 been the only inmates, it might have been "considered" that water containing one grain of lead in a gallon was "quite innocuous," and might be consumed without risk. Some persons are undoubtedly more susceptible of the effects of lead than others: a few may suffer in three or four months; others, as Dr. Christison states, not until after twelve months. The public health, however, must be protected, even although not more than one person in twenty might sustain injury from the use of the patent sugar or treacle, and although it might require many months to produce serious effects on the human constitution. It is a case in which we believe it to be impossible to obtain any fair criterion of safety except at very great and unnecessary risk.

THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

THE eighteenth anniversary meeting of this Association took place at Hull on the 7th and 8th of August, and was very fully attended by medical practitioners from all parts of the kingdom. Dr. Horner, of Hull, took the chair which was vacated by Sir Charles Hastings. An appropriate address was delivered by the President, and the Report of the Council on the various subjects which have occupied the Association during the past year was then read. Several of these, with the reports thereon, have already found a place in our pages. From the financial statement it appears that the affairs of the Association are in a very prosperous condition.

The statement of accounts is as follows:—

Balance in hand	£	16	2	6
Receipt	.	1616	4	2
Total	.	1632	6	8
Expenditure	.	1522	8	2
Balance in hand	.	109	18	6

We are glad to find by this report that a committee has been appointed to draw up a code of *medical ethics* for the government of the Association, which we believe now numbers upwards of 1500 members.

Brighton has been fixed upon for the place of meeting in 1861, and the anniversary address will be delivered by Dr. King.

Hospital and Infirmary Reports.

ST. BARTHOLOMEW'S HOSPITAL.

Two Cases of Cancer of the Penis—Amputation.

O. HAWKINS, a stable-man, *æt.* 46, in the habit of drinking beer and gin freely: has had syphilis several times, but not within the last few years; has never experienced any difficulty in withdrawing the foreskin; about nine months ago discovered a sore on the lining of the prepuce, and showed it to a surgeon, who administered mercury and salivated him: the sore, however, continued to spread; and he left off the medicine, and did not seek any further advice until July 12, 1850, when he came to St. Bartholomew's Hospital, and was admitted under Mr. Lloyd. A large irregular ulcer, with thick edges, covered here and there with small florid granulations, and with a foul thin discharge, occupied the whole extremity of the penis; the glans was entirely destroyed; the remainder of the penis was hard and swelled, and the skin was red and thick. The glands in the groin were not enlarged. There was a varicocele on each side. The hardness of the penis extended so far back that there was some difficulty in determining whether all the disease, which was decidedly malignant, could be removed: this, however, was considered practicable, and the only means of stopping its progress, and was therefore recommended to the patient.

Aug. 6th.—Chloroform was administered, and Mr. Lloyd divided the integuments around the root of the penis, so as to separate it from the scrotum and pubis, and then, drawing the organ forwards, divided it just in front of the symphysis. The entire diseased structure was removed. A few arteries were tied, and a gum elastic catheter was passed into the bladder, and secured from slipping out.

19th.—The patient is going on well; the wound is suppurating and granulating kindly; the catheter remains in the bladder.

John Bradford, *æt.* 69, a cook, residing in London, has had a sore on the penis for nine years, which commenced on the lining of the prepuce, and gradually spread to the glans and orifice of the urethra, and occasioned a great deal of pain in making water; has always had phymosis.

Aug. 9th.—Was admitted into St. Bartholomew's Hospital, under Mr. Skey: the prepuce could not be drawn back, and was therefore divided, and an ulcerated surface, from which sprung an irregular shaped

nodulated diseased mass, having the appearance of an accumulation of warts, with a thin foul discharge, was exposed on the extremity of the penis in the place of the glans which had been destroyed. Several glands in each groin were hard, and slightly enlarged. As the disease extended very little beyond the glans penis, and the remainder of the organ appeared sound, and as its character was decidedly malignant, amputation was advised and consented to. **17th.**—The patient was brought under the influence of chloroform, and Mr. Skey divided the penis, about its middle, with one stroke of the knife: a few vessels were secured, and he was sent to bed.

Removal of the Head of the Femur.

Ann Sugg, *æt.* 13, fell over a skipping-rope about three years ago, and received some slight contusions about her left hip; inflammation of the joint followed: she was unable to use the limb, and suffered a great deal of pain in the knee. About a year after the accident she was able to limp about, but could only get the toes of her left foot to the ground, as she was unable to extend the knee or hip joints. In a few months abscesses formed around the hip, and burst; and for the last seven months some of them have remained open.

June 6th, 1850.—Admitted into St. Bartholomew's Hospital in an extremely emaciated condition, and nearly worn out with suffering. The left femur was dislocated on the dorsum lili, the limb shortened, and the leg and thigh flexed: there was a large ulcerated surface over the trochanter major, through which the bone threatened to protrude, with burrowing sinuses in the neighbourhood discharging pus freely. After being in the hospital a few weeks the child gained a little flesh, but she has lately fallen off again, not being able to stand the pain and continued discharge of matter from the wound. It was considered that removing the head of the bone would give the patient the best chance of recovery; and the operation was performed on August 17th, by Mr. Skey, the patient being under the influence of chloroform. As the end of the bone was only thinly covered with granulations, a very little cutting sufficed to expose it; this being accomplished, the limb was carried inwards, and the bone divided with the saw just below the great trochanter. The granulations bled freely on being cut, but the hemorrhage soon ceased, and no ligatures were required. The integuments were too firmly adherent to the parts beneath to admit of being drawn together; the wound was therefore left open.

The acetabulum was found to have been enlarged by absorption, and was extended

in a direction upwards and backwards, as if an attempt had been made by nature to form a new joint in this direction. The head of the fetus had been entirely absorbed; a portion of the neck remained, which, with the great trochanter, was the part removed: on dividing this with the saw it was found to be soft, and composed of vascular cancellous structure, with a very thin outer layer of compact bone.

Excision of a Malignant Tumor from the Thigh.

O. T., *et. 69*, a commercial traveller, with a florid complexion, singularly formed head, simple expression and manners, has always enjoyed good health, and been in the habit of taking strong walking exercise, states that three months ago he first experienced a painful sensation in the front of his right thigh, and soon afterwards discovered a lump there the size of a cob-nut, which has gradually increased.

He was admitted under Mr. Stanley on July 30th. A tolerably firm tumor about the size of an orange, over which the integuments readily moved, tender on pressure, and sometimes so painful as to prevent his sleeping, was embedded in the muscles on the front, and one-third from the top of the right thigh. The glands in the groin were not enlarged. Its removal was readily consented to.

August 10.—Mr. Stanley exposed the tumor by a vertical incision: it was situated in the rectus muscle, from which it readily separated, and was quickly removed. On examination, the tumor was found to be of a malignant character.

19th.—The wound is granulating, and the patient going on well.

Excision of a Chronic Mammary Tumor.

M. G., *et. 26*, a healthy unmarried girl from the country, states that five months ago she received a blow on the inside of her right breast, which gave her a little pain at the time, and was soon forgotten. Three weeks after this, she accidentally discovered a small lump, not quite so large as a nutmeg, in the same situation, which has gradually increased in size, but has not been at all painful.

August 3rd.—Was admitted under Mr. Stanley. A tumor the size of a small orange, firm, but not hard, and very moveable, was situated immediately beneath the skin and on the inner side of the mammary gland, which was quite healthy: none of the neighbouring glands were enlarged, and the tumor had every appearance of being non-malignant. The patient, however, was anxious to get rid of it; and on Aug. 10th its extirpation was effected with the greatest ease while she was under the influence of

chloroform. The wound was closed, and is now (Aug. 19) granulating and healing fast. The mammary gland was uninjured. The tumor was one of those which have been described as chronic mammary or pancreatic, as their structure somewhat resembles that of the pancreas.

PROPOSED EXHIBITION OF ETHER VAPOUR TO THE DYING.

OUR new contemporary, the *New York Medical Gazette* (July 18), in commenting on Dr. Warren's valedictory address, condemns his proposition to administer ether vapour to the dying for the purpose of easing the pangs of death.

"The agony of death," observes Dr. Warren, "is a fair subject for the influence of ether. This supposed agony, in the greater number of cases, perhaps, is a creature of the imagination, conjured up by fear. Nature, like a kind mother, has presented the phenomena of death with such accompaniments as she thinks necessary to deter us from resorting to it by our own act. But while the entrance to the dark passage appears frightful, as we pass on it becomes less and less distressing, till it terminates gently in insensibility. Some instances there are in which there is no real suffering. In these we have an invaluable friend in ether. And when the mortal strife is so far advanced as to leave no hope nor chance of recovery, the duty of a physician is to interpose the means by which we may be softly and agreeably conducted through the final moment. This practice I adopted many years before ether was introduced into surgery, and I have followed it lately, though with great caution, and never without the clear knowledge and full assent of friends."

On this our contemporary remarks:—"God forbid that any physician should ever assume to know infallibly that 'there is no hope or chance of recovery' in any case; for as learned and experienced men as Dr. Warren himself have often been mistaken on this point. And should the discovery of ether lead to the general or frequent use of this 'means of conducting' those who are supposed to be dying 'through the final moment,' it were better for the next generation that the discoverers had never been born. No 'knowledge, or full assent of friends,' in our opinion, can justify such a practice."

. We must also strongly express our disapprobation of the extraordinary proposition made by Dr. Warren. If the plan were adopted it would give rise to the greatest criminal abuse. It is the law in this country, that whatever accelerates death causes death, and a practitioner thus using ether vapour might find himself subjected to a charge of manslaughter.

Medical Trials and Inquests.**CUMBERLAND ASSIZES.**

Carlisle, August 3.

Before Mr. Justice Wickham.**Trial on a charge of Manslaughter for Poisoning by Lobelia Inflata—Acquittal of the accused.**

Wm. TAIT was charged with the manslaughter of William Hewitt, at Parton, on the 19th of June last, by administering to him a certain quantity of lobelia inflata, mixed with water. Prisoner pleaded Not Guilty.

Mr. JAMES and Mr. HODGSON appeared for the prosecution, and Mr. Sergeant WILKINS for the defence. Witnesses, at the request of Mr. Sergeant WILKINS, were ordered to leave the court.

It appeared, from the statement for the prosecution, that prisoner and deceased were fellow-workmen at an iron-foundry. Deceased was 25 years of age, and a man of good health. About five weeks before this occurrence he had had medical attendance for a slight gastric disorder of a temporary kind. From this he speedily recovered, and was engaged at his work as a founder until Wednesday, the 19th of June. He returned home at eight o'clock in the evening, and, it seems, complained of heartburn and indigestion. About ten o'clock that evening, the prisoner was seen mixing something in a cup, which he said was *lobelia*. The deceased was at the time in bed. The prisoner gave this mixture twice to deceased, and in about half an hour it produced vomiting. The vomiting continued, more or less, from that time, until the deceased died on Friday afternoon; but there seems to have been a remission of the symptoms on Thursday afternoon, so that deceased was able to get up and go out. The deceased had no convulsions or fits of any kind, and retained his senses until the last. The colour of the matter which he vomited was green. His stomach was much swollen. On Friday morning, as the deceased was very unwell, the prisoner was sent for. He came, and gave deceased some more medicine, the nature of which was unknown. Deceased subsequently had some small beer, which had been fetched from a neighbour's. It appeared that he had had some beer on Thursday, which a witness described as having a sharpish taste. He also had more medicine from the prisoner on that day. In fact, it appears that he had been

dosed with medicine by the prisoner from Wednesday night until Friday morning, when he was first seen by Mr. Hilton, a medical practitioner. We subjoin the medical evidence:—

John Bateman Wilson examined by Mr. HODGSON.—I am a member of the College of Surgeons, and practise at Whitehaven. I attended deceased about six weeks before his death. At that time he had a slight stomach complaint which is generally called spasm, produced by flatulency and wind on the stomach. I prescribed for him on that occasion, and he was relieved in the course of half an hour. I saw him again on the following morning, and he was so much better that I did not visit him again. He appeared to be a healthy man. On the morning of Friday, the 22nd of June, deceased's brother came to me, requesting me either to visit him or send him something. I sent him the same medicine which I had previously administered to him,—namely, two doses of calomel, the one to be given three hours after the other if he did not feel relieved. From what his brother said, I considered he was suffering from his former complaint. I got a friend to go that morning at eight o'clock to see him, and I went myself at three o'clock in the afternoon. When I saw him he was in a state of prostration. He was conscious, and recognised me, and held out his hand to grasp mine. From his being in such a reduced state, and from being two miles from my residence, I ordered a little brandy and water, for the purpose of supporting him as much as I could, although I knew it would be of no use, as he was then in what medical men call the sinking or the dying state. He was dead when I returned. There was no message sent me, and I returned between six and seven o'clock to make further inquiry, and he was dead. From the symptoms attending his death I considered he died from the effects of a poisonous substance. I form that opinion from his having been perfectly well on Wednesday, before he had something given to him, from the fact of death occurring so rapidly, and from what his relatives told me. I visited him on Monday, the 17th June, on account of an accident which happened to his finger. He appeared then in general good health. He made no complaint, nor did he look ill. After his death I thought that further inquiry should be instituted. I made a *post-mortem* of the deceased. Mr. Thompson assisted me on that occasion, and there were present two other gentlemen. The external examination of the body demonstrated a muscular young man. On removing the body from the bed to the table a quantity of fluid issued from the mouth

containing *vegetable matter*, which had a very sickly odour. A portion of the fluid I retained for further examination. On opening the chest we found the heart healthy. The lungs were congested at the posterior part. There was nothing else remarkable about them; but, on opening the abdominal cavity, we saw, through the coats of the stomach, a collection of a dark substance, which we likewise observed in various parts of the bowels. It was a *dark greenish powder*. His stomach I removed for more minute examination, and a portion of the bowels as well. In another portion of the bowels I found small patches of *this vegetable powder, with redness under these patches*. The liver was pale, and what we call flabby or soft. The gall-bladder contained a quantity of dark and thick bile. The spleen and pancreas presented no unnatural appearance. The kidneys looked paler than usual, but in what we call the lower portion, and in each of them, two drops of matter were found. On examination of the brain there was found some congestion, but not more fluid than usual in the ventricles. The stomach and a portion of the bowels I took care of and locked by. At a later part of the evening, with the other gentlemen, I examined the stomach. On opening it, the same disagreeable sickly smell issued from it. The stomach was *generally inflamed*; and there were *patches of vegetable matter, and under these there was a vivid redness. A portion of the bowels was likewise found red*. There was also the same smell, though not so distinct, as in the stomach. I applied a test with respect to this vegetable matter. I used nitric acid, which produced a reddish-brown colour, and sulphuric acid, which produced a dark brownish appearance. These two together go to show there was the presence of vegetable matter. They have been recommended as tests for lobelia, but they are tests for other vegetable matter, and I do not consider them alone sufficient tests for lobelia. From the tests applied, and taking all the circumstances into consideration, I consider that *deceased died from the effects of a poisonous irritant, causing inflammation of the stomach*. I have seen a powder called lobelia, but have not been in the habit of using it. It has a peculiar smell. The smell which issued from the stomach was that of lobelia. I purchased lobelia that evening, and then I found that it had the same smell as that which proceeded from the stomach and mouth of deceased. I never was in the prisoner's company except before the coroner and magistrates. Cross-examined by Mr. Sergeant Whelan.—I do not recollect that I ever administered lobelia in my life. I know it is a native of

America. It is used extensively there in dangerous doses. Its principal use is as an emetic. I may put it under the same class of smells as that of new-mown hay. It was about three weeks previous to the 21st of June that deceased injured his finger, and after I attended him for his stomach complaint. Supposing the finger continued to suppurate and exhibit proud flesh up till the time of his last illness, it would not indicate an impure state of constitution. Supposing that the finger was injured a month before, and continued to make proud flesh, and no healing process had begun at the time of death,—I say again, as I value my reputation, that it would not argue an improper state of the fluids. The healing process generally commences in about a week or ten days, but this case did well. The coat of the stomach is irritable in its nature. Spasm is created by an inordinate extension or contraction of the stomach. Spasm is the result rather than the cause. Want of proper action in the system will produce wind and flatulency. Indigestion will cause a want of action in the system. I never knew a case of indigestion where the food remained in the stomach until it was in a putrescent state. You may call it putrescent sometimes, when it is a while in the stomach without being digested. I never saw or read of a case where food remaining on a weakened stomach has produced all the irritating consequences of vegetable poison. I have known a person to die of Asiatic cholera. I have known two fatal cases of British cholera, but never had any of my own. When persons die of British cholera, it is produced by irritation of the stomach and bowels. Death from such a cause is sometimes sudden. Supposing I had known nothing of lobelia, and had not known that deceased had taken it, I would have attributed his death to some direct irritant applied to the stomach. Supposing the stomach to have been for a long time unemptied, and the food remaining in it till it was putrescent, that would not have been an irritant directly applied to the stomach, for there would have been purging with it. The very fact of constipation of the bowels would not act on the stomach and prevent purging: inveterate constipation, however, would. I do not know that deceased had no motion in his bowels for nearly three days. He had a motion on Wednesday. I know this by questioning his brother when before the magistrates. The circumstance of the gall-bladder being full of dark thick bile indicated that: here had been some obstruction to the complete flow of bile from the gall-bladder. In some individuals, it is the reverse, and the bile not

spread as it should be, irritation of the most dreadful kind will be produced; but I have not seen or heard of irritation of that kind producing death. I found some pus in the kidneys. The kidneys were healthy. There was nothing in the kidneys but that pus: it indicated inflammation. Irritation will produce inflammation, which will lead to the formation or deposit of pus in the kidneys. When Thomas Hewitt came to me he told me his brother's stomach was swelled in the same way that it was when he was at Whitehaven. *By Mr. Hodgson*—It is my decided opinion that death arose from nothing else but this vegetable matter which had produced inflammation. *By His Lordship*—I have never administered lobelia myself. I have, however, seen it administered, but never in doses exceeding from ten to twenty drops when in the form of tincture. It has been used in cases of asthma, for the purpose of producing vomiting and affording relief to the chest. *By Mr. Sergeant Wilkins*—I know that Taylor recommends eighteen to twenty grains as a dose.

William Richard Hilton, examined by Mr. Hodgson—I am a surgeon at Whitehaven. I attended deceased about half-past nine o'clock on the morning of the 21st of June. When I got there he was complaining of a burning pain. There was a good deal of cramp in the stomach and severe vomiting. He vomited very frequently while I was there. *What he vomited appeared to be a greenish brown vegetable powder.* In consequence of what he told me of his symptoms, I prescribed soda-water to be taken immediately to allay the vomiting; I ordered an injection; I prescribed also some pills the effect of which was to relieve vomiting, from whatever cause it proceeded. I was present at the post-mortem examination. *[Mr. Sergeant Wilkins said that it would not be necessary for Mr. Hodgson to go into the post-mortem examination with the witness. He then proceeded with the cross-examination of Mr. Hilton:]*—The case of the deceased was not attended by all the symptoms of violent cholera: there was no purging in this case at all. I did not administer the injection and blister, but I believe they were administered. After the administering of the injection I did not see the contents of deceased's bowels. I would not call lobelia a pure narcotic; it is a narcotico-irritant poison. Lobelia is a medicine very much used in the United States of America: it is used as an emetic there. I know that it is given there in larger doses than a scruple: it is given in dangerous doses. Twenty drops of tincture will contain about two grains of lobelia. Supposing I had visited a patient, and found

him labouring under the influence of lobelia, I would have given him an emetic if he had taken a large quantity. Dyspepsia means disordered digestion. If a stomach labour under the duties it has to perform for some time, it will be certainly weakened in its powers. The stomach is not as irritable as the pupil of the eye. Without comparison, it is exceedingly irritable. I have been ten years studying and two years in practice.

John Thomson, examined by Mr. Hodgson—I am a Member of the College of Surgeons, and practise at Whitehaven. I was present at the post-mortem examination of deceased. I have frequently prescribed lobelia. *Cross-examined by his Lordship*—In large doses, I should call lobelia a narcotico-irritant poison. It is used as medicine in small doses; in cases of asthma it is used as an anti-spasmodic; it is also given as an emetic. From what I observed at the post-mortem examination, I think deceased died from the effects of an irritant vegetable poison. *By Mr. Sergeant Wilkins*—Lobelia has been used here for some years in small doses: its nature is not so well understood as that of other medicines. I know there are some very eminent medical men in America: I have heard that lobelia is commonly used there in large doses. I found, at the post-mortem examination, that the internal coat of the stomach was a good deal inflamed; in this case, the inflammation was not produced by the deranged state of the stomach. Supposing the stomach to have contained food for some time in an impure state, inflammation would have been produced, but not such as in this case, where it was in patches. I have got none of the stomach now: by this time it will be decomposed. I did not think it was necessary to preserve any of the vegetable matter. *By Mr. Hodgson*—Lobelia is a most dangerous medicine. *By his Lordship*—It has a peculiar smell. I have felt the smell of what is sold in the shops as lobelia, and the smell which issued from the stomach of the deceased was the same.

Richard William Broster, examined by Mr. Hodgson—I am a surgeon at Whitehaven, and attended the post-mortem examination of William Hewitt. From the symptoms I observed on that occasion, I consider deceased died from inflammation of the stomach. I would consider it was caused by what was found in the stomach. I believe it was lobelia. I never had anything to do with lobelia myself. I consider lobelia to be an irritant: I would designate it a narcotico-irritant. I consider it a dangerous medicine.

Mr. Sergeant Wilkins then addressed the jury on behalf of the prisoner. He

said it was a fortunate thing for the prisoner, who was as respectable and respected a young man as existed in this country, that he was not to be tried by members of a profession who were always aroused by anything which threatened to interfere with their profits or their prejudices. It was a matter of history, and he said it advisedly, and begged the attention of the jury to the fact, that the medical world had done more to impede the progress of medical science than all the rest of the world put together. It was a remarkable fact that the greatest men which the medical world had ever produced had, in their day and generation, been persecuted and scandalised when they dared to stand out from the beaten track of the profession. They had been told that Tait was simply a man who wrought in a foundry, as if that were to be urged as a reproach against him. It was a notorious fact that the man who had made the greatest discovery of the age in medical science was a blacksmith in Germany—the author of *hydropathy* was Priesnitz, and he hoped to see the day when *hydropathy* would be fully carried out. They had it in evidence that this medicine, called *lobelia*, was making rapid progress in America. There, where they had first-rate medical skill, it was becoming general and universal in its application. And who were the men to call it a dangerous medicine—who were the men to impugn its effects? In this evidence, which it was shocking and revolting to contemplate, an attempt was made to convict the prisoner of felony on the evidence of men who knew no more about *lobelia* than any one of the jury. The gentleman who had been last examined had never used it in his life. One had seen it administered by others, but had never administered it himself; and the first gentleman (Mr. Wilson) said he was not likely to run the risk of poisoning his fellow men by using it. Not one of them had described it. What had they learned from these four medical gentlemen that they did not know before? They had said that *lobelia* was used in dangerous doses in America. How did they know that? They had never tried the experiment. The medical doings in America were as well known in this country as were the legal, commercial, and philosophical doings of America; and why, therefore, had they never heard of this before? When a man prescribed four grains of calomel he did it on the authority of experience—he did it on the authority of some cases stated

in the medical world. Almost everything done in the medical world was based on precedent: the men did not think for themselves; they learned the uses of the various medicines from their books: their pharmacopœias told them that the use of such and such medicines were proper in such and such cases, and they shaped their course accordingly. And what had this man done more? There was his authority. He said—"I fetch Mr. Wilson, the man who institutes this prosecution, and Mr. Wilson himself tells you that in America it is largely used, and that in what he calls dangerous doses." If it was attended with such very great danger in America, why did they not hear of its being productive of mischief? Let them, however, take a short history of the case itself. Let them look at the position of the prisoner and deceased. They were on friendly terms with each other. Deceased had gone to the prisoner—the prisoner had not obtruded himself on deceased. The father, brother, and sister, said that he became sick within half an hour after the prisoner first gave him the *lobelia*, and that he continued so up till the time of his death. That could not be if they believed the father possessed the feelings of a father. If he had thought that the prisoner had given him anything wrong, why did he send for him again? The prisoner had been most attentive to him—had been with him on one occasion for three hours—had gone when sent for during the night, and not a farthing was he to get for his trouble. If he had asked the medical men separately what they would have given deceased in the circumstances in which he was placed, he laid his life to a shilling that every one of them would have given a different prescription. It would be best for society if post-mortem examinations were more frequently held; and he took it for granted that if some of these gentlemen were subject to post-mortem examinations, the result would not be very much to their credit. Six weeks before this death happened deceased had cramp, as it was called, in the stomach, which produced those spasms the medical men said were the result of wind and flatulency. But what produced wind and flatulency? If indigestible food were allowed to remain on the stomach, fermentation ensued, and impure gases arose, and the stomach became subject to spasms or cramp, and that was not unfrequently followed by death. He took it on him to say, that on a perfect stomach wind never existed. Deceased had an imperfect stomach, and he said that his food

* It is making "a rapid progress," but not in the sense implied by the learned Serjeant. The "progress" is in the hands of quacks, to wit in reducing the number of the population.—Ed. Gaz.

putrescent; and hence the comparative sudden death of this man. A man's food would often be his poison if his digestive organs were not in a proper and healthy condition. A lobster would poison a man—not that the lobster itself was poison, but that, remaining on the stomach undigested, it would in a short time be productive of all the consequences of poison, from the *supere and putrescent state to which it must become reduced*. They had many instances on record of persons dying from the effects of constipation, produced by the overloading of the stomach. And what evidence was there, from the beginning to the end of this case, to make them believe that the death of this man did not ensue from a similar cause? He asked Mr. Wilson why he did not bring some lobelia here—nay, why did he not bring some of that vegetable powder found in deceased's stomach? "It was not necessary." Not necessary! Why, the jury were called upon to decide a matter materially affecting the character and happiness of a fellow-creature—a man accused of felony, and yet Mr. Wilson did not think it worth while! Did he think the jury were going to take for granted all he said? They had no respect of persons; they sought to get at the truth; and it was necessary they should have all that could assist them in getting at the truth. He asked again, what evidence was there that, except upon one occasion, the prisoner ever administered lobelia to the deceased at all? The only evidence they had was, that he gave two doses on Wednesday night within a quarter of an hour of each other; there was not a tittle of evidence that he gave any after. How much was given? One grain, two grains, three grains?—a spoonful, or a drachm? They did not know; there was no evidence. He asked one of the medical men this: "Suppose you had come to this patient, and found him labouring under the influence of lobelia, what would you have done?" He said—and he prayed the jury's attention to this—"I would have given him an emetic if I had thought it had been too large a dose." Clearly he did not think he had had too large a dose of lobelia, because he did not give him an emetic. "But if you had given him an emetic, what would it have been for?" "Why, to make him sick." "What would have been the effect of making him sick?" "To throw up the contents of the stomach." Ah! but those people said there was no occasion for that, because the man had been sick for twenty-four hours. If, then, no lobelia had been given to this man for twelve hours before his death, and during that time he was constantly sick and throwing off the con-

tents of his stomach, how happened it that any lobelia was afterwards found in his stomach at all? But he took a basin of cold sour small beer that morning. The jury all looked like healthy men; but would any one tell him whether he would venture to take a basin of cold sour small beer at five o'clock in the morning, or, if he did, whether he would not expect spasms, cramp in the stomach, and other violent symptoms that showed themselves in the deceased's case? Again, he reminded them that there was no evidence to show that after Wednesday night deceased took one grain of lobelia into his stomach, and none to show how much he took on Wednesday night, or whether it was a dangerous dose; besides, not one particle of what he did take would be left in his stomach if vomiting produced the effect that the medical gentleman said it did. What did they find in the stomach? "Some vegetable matter." "Was it poisonous?" "They did not know." Potatoes, greens, onions, were vegetables; they could not tell whether it was any of these. All they knew was, it was "vegetable matter," and that under it, in some parts of the stomach, were signs of irritation. Whether it was lobelia, or whether it was decomposed vegetable matter, lodged in the stomach from imperfect digestion, none could tell. (?) Again, what was deceased's treatment? What was his complaint? Spasms. What was lobelia? An anti-spasmodic. What besides? He complained of heartburn; that came from indigestion, from the stomach being oppressed and loaded. Common sense taught them that the remedy for that was to unload the stomach. The doctors admitted that lobelia was an emetic, and given in America in large doses by medical men. *Why, then, the thing to be done was the very thing that was done in this case.* Another circumstance: the gall-bladder contained, when the body was opened, a quantity of thick black bile. He asked Mr. Wilson—"How long, in your opinion, was that bile undisturbed?" "Eighteen hours," was his reply. "How long, in your opinion?" he asked another young gentleman. "Three or four days." He took it upon him to say the latter was more correct. Well, then, if, after all their remedies, their calomel, their injections, their hot applications, the gall-bladder was so inert, what stronger proof could he have of an impaired digestion and want of power of relieving the body of its feculent contents? What was the use of the gall? To promote, by lubrication, the motion of the intestines. If a man had no motion for twenty-four hours, or more, could they wonder at pain, or even spasms, ensuing? And could they wonder that much reliance

could not be placed upon gentlemen who differed so much, one saying eighteen hours, and another three or four days, by those who had been behind the scenes, and knew something of the profession itself? One medical gentleman told them that, with the exception of purging, deceased exhibited all the symptoms of cholera. Why, *the absence of purging might have produced all the symptoms seen.* Let them look at it mechanically. After mastication, the food passed into the stomach; the contents of the stomach must have free access to the bowels; if in the bowels stoppage takes place, a check ensues on the stomach, the bowels act upon it sympathetically, and produce nausea and increased disease; and if the stomach be allowed to retain its contents, a sickly smell will ensue. If the jury had ever laboured under indigestion, they must remember how their mouths tasted, and how the edges of their lips sometimes grew sore. The mouth itself sometimes became ulcerated from the same cause. They had seen how children frequently suffered from their foolish parents giving them improper food. Men were but "children of a larger growth," if they indulged themselves in the same way, the same effects would be produced.

He had, he thought, now gone over all the facts of the case: he came now to the law. The opinion of one learned judge had been quoted: he would quote another. In the case of the Queen v. Winterbottom, at last Liverpool assizes, before Baron Alderson, that learned judge said, "*The question for the jury to consider was, whether the prisoner had done what he considered most advantageous for the recovery of the patient? if he had done so, he ought not to be declared guilty of manslaughter.*" Unless the prosecutor (continued his lordship) made it plain that the prisoner was *not doing his best*, there was an end of the case: and if people employed unqualified persons to dispense medicines, they themselves must take the consequences." Now that, he (Sergeant Wilkins) submitted, was *good law*. There was no law to prevent any one practising; and this case was not, as his learned friend had suggested, one in which medical attendance was at hand, and the prisoner obtruded himself on the patient, and so excluded professional attendance, but one in which the prisoner had been invited by both the deceased and his father. Would any one doubt that the young man did what he conceived to be right and best under the circumstances, and that the result came not *through any gross negligence or want of proper care on his part*? He was a friend of the deceased, and had every desire to save him. He stood high in his position of life,

having been *five years* in his present employ, with a character unimpaired and unimpeachable, and he (Mr. Sergeant Wilkins) did hope and trust that they would feel themselves justified in saying that there was *so much* doubt and difficulty in this case, and the possibilities and probabilities, least in so many directions, that they could not convict the accused as conscientious men, having a regard to their own interest, and that of others.

His LORDSHIP then charged the jury. The prisoner, he said, was accused of manslaughter, by having administered to the deceased a certain quantity of a noxious drug called lobelia, by the effects of which death was said to have ensued. Now, whatever might be the result of this inquiry, he felt himself called upon, in justice to the prisoner, to say that there was no imputation whatever on his motives. His feelings towards the deceased seemed to have been of the very best and most friendly kind; he acted quite gratuitously, and with a view, as he said, to do him good. So far, therefore, *there was no imputation whatever on the prisoner's motives.* But the law, as he understood it, was this, that if an ignorant and unskilful person undertook *voluntarily, and without necessity,* where competent medical assistance could be procured, to administer drugs of a *poisonous or dangerous nature*, and which required the greatest caution and skill in their use, and the patient should die in consequence of the *ignorant and unskilful* use of such drug, the party who administered that drug did so at his own risk, and would be guilty of manslaughter, notwithstanding that he administered it, believing that it would turn out to be beneficial. Now, in this case a great question for their consideration was, whether they were perfectly satisfied that the deceased died of lobelia? because if they were not satisfied of that, the rest of the case need not be considered, the charge being that he died of that noxious drug as administered by the prisoner. Should they be of opinion that he did die of lobelia, the question would then be whether the prisoner at the bar, in administering that lobelia, administered it, under the circumstances, ignorantly, presumptuously, unskilfully, and without that due care and caution which every one was required to act with who professed to deal with such drugs. Now, this drug called lobelia appeared to be but little known in England until lately—in deed, it was not very much known now. It was said to be extensively used in America, and in larger doses than in England. It was in use in England by regular medical practitioners as an anti-spasmodic, and also as an emetic, and its qualities

were such as had induced the scientific world to class it among what were called the narcotico-irritant poisons. When administered in large doses, and under improper circumstances, the effects of these drugs were such as many persons were unable to endure. Many drugs, even in the most common use, were, when given in large doses, and under improper circumstances, most deadly poisons. Hence the skill and care required in administering them. Now, the prisoner at the bar did not profess the practice of medicine. He was employed in a foundry, and was a fellow-workman with deceased. On the whole, the judge seemed favourably impressed towards the prisoner, and concluded by again putting the question before the jury:—*viz.* whether they were satisfied, upon the evidence, that the prisoner died from natural causes, as *indigestion*, however produced, or by the undue, improper, careless, and ignorant administration to him of lobelia by the prisoner? If satisfied that he died from the latter cause, they would find him guilty; but if they were satisfied he died from natural causes, they would acquit him.

The jury then retired, and returned in about ten minutes with a verdict of *Not Guilty*. On the foreman pronouncing the verdict, a murmur of satisfaction arose in the court, which the court officer immediately suppressed.

On discharging the prisoner, the judge remarked that whatever might have been the result in this instance, the motives of the prisoner had been perfectly good, though it was to be hoped that all parties of insufficient education and skill would for the future be cautious how they dealt with such drugs as this.

Correspondence.

ON THE NATURAL PERIOD OF UTERO-GESTATION.

SIR,—On Jan. 25 you published my report of a case in which the secretion of milk had occurred at an unusually early period of pregnancy. The sequel of this case may not prove uninteresting, throwing some light, as it seems to me, on questions not altogether resolved as yet, if indeed they are capable of solution by our limited reasoning powers.

The subject of the report alluded to was after a very short and easy labour delivered of twins on the 8th day of May, 1850. The children were and still are both fine and healthy infants.

Now supposing that conception did really take place on the 12th of August, 1849,—and I need not enter into my reasons for accrediting M. F.'s statements, which are detailed in my former communication,—it is worthy of remark that the period of utero-gestation exactly corresponded with that which is now generally looked on as its average duration,—i. e. nine lunar months of 30 days each, or 270 days, including, as is usual, the first and last days of pregnancy, or those of conception and delivery.

Again, when a healthy young woman is, in her first confinement, delivered after a natural labour, it is not unfair to argue that the duration of her pregnancy was of average length; the less so when it is remembered that the time when quickening took place is in a most unsuspecting manner fixed for a period anterior to delivery by 22 weeks and a half, "*Quam proxime*" (vide No. for Jan. 25, 1850, p. 145), which, with 16 weeks, the interval from conception to quickening, generally allowed as a fair average, make 38 weeks and 4 days, or the above average duration of natural pregnancy. Thus I conceive the chain of reasoning becomes the more strengthened by the mutual fitness of its links to each other; and what, on the 27th of Dec. 1849, was merely a very probable assumption, may now be looked on as an established fact; and we may give full credence to her statement, that on Sunday, the 12th of August, 1849, she being in expectation of the catamenial flux on that day, allowed the approaches of her lover, not absolutely for the first time, but for the first time since many months; *that coitus*, notwithstanding the menses appeared and lasted their usual time (with her) till the 15th or Lady-day, which, being a great holiday, served with her as an epoch from which to count. *En passant*, it may be remarked that this gains additional probability from the fact that, while she is a Roman Catholic, her seducer is a Protestant, and thus Sunday was the only day on which they were both likely to be at liberty in the early part of the day, when intercourse is stated to have occurred. That a day or two before the 1st of December the train of symptoms usually existing before the uterus rises out of the pelvis, had, in a rather sudden manner, been considerably relieved, and in fine, that on the 8th of January, 1850, she actually was, as every thing considered she was pronounced to be, in the latter end of the 21st week of pregnancy. It now remains to be considered whether any additional evidence can be offered in support of the fluid secreted by the mammary glands at this early period and in abundance, being *bonâ fide* milk.

Upon this I may remark, that having

since that time become much more familiar with the use of the microscope, and having examined the milk of women nursing, and at very different periods after delivery, I am prepared to assert that it was not only real milk, but a milk very rich in oil globules; in fact, a very creamy milk.

The only circumstance that seemed to throw a doubt on its real nature was the fact of its showing an acid reaction so soon after it was taken from the breast. On this point I have to remark that, shortly after the date of that observation, and in consequence of my attention being drawn to the subject, I met with a case in which, in a remarkably healthy woman, and a fine nurse, the milk was actually and energetically acid at the breast, reddening litmus paper instantly on being milked immediately on it. This woman had been nursing for the long period of two years and about six weeks; still both she and her nursing were in good health. I have lately met with a case in which, in a young and healthy woman (a well-fed person too) in whom, seven days after her second confinement, the milk at the breast was scarcely alkaline (this so marked in my note-book), in three-quarters of an hour it was neutral; and in two hours after it was drawn it was faintly acid. This was a very rich creamy milk, and under the microscope reminded me strongly of that of M. F., which was the first human milk I had ever examined in this way: indeed, I am inclined to think that further observation may furnish some not merely solitary exceptions to the generally received maxim that human milk is, when freshly taken, always alkaline.

You will use your own discretion in inserting or not the above observations, and believe me to be,

Very faithfully yours,
J. I. TRAYER.

Dunow, Queen's County,
August 16, 1860.

Medical Intelligence.

THE NATIONAL INSTITUTE AND THE SOCIETY OF APOTHECARIES.

THE Committee of the Council of the National Institute have agreed to the following resolution:—"1. That this Committee, having considered the propositions contained in the letter from the Society of Apothecaries to the Right Honourable Sir George Grey, Bart., for altering the Apothecaries' Act of 1845, hereby declare, that

they cannot support any scheme for regulating the education and conducting the examinations of the general practitioners in medicine, surgery, and midwifery, which is incomplete, or which does not embrace all the branches of education and practice necessary for the efficient performance of the duties of general practitioners. That, in particular, the Committee repudiate the remodelling of either of the existing institutions (as they have, hitherto, the establishment of any new institution) that is not based upon the unity of medicine and surgery, and which, in the education and examination for admission into such institution (which is also intended to confer a title to practice) does not embrace all the branches both of medicine and surgery. 2. That the want of proper authority to examine in surgery has, at all times since the Act of 1816, operated prejudicially upon the examinations instituted by the Society of Apothecaries; and that this Committee unequivocally condemns any proposition to alter that Act which does not embrace an amendment in this essential point. That the unity of medicine and surgery has been the fundamental principle of the National Association and of the National Institute, and has been consistently adhered to throughout; and that, without questioning the right of the existing institutions to retain their special character, the Council resolves to adhere to this principle in reference to the education and qualification of the general practitioners as essential to any measure of medical reform."

FEMALE DOCTORS IN THE UNITED STATES.

WITH the exception of Madame Restall, which is the *nomme de guerre* of a notorious abortionist, and one or more of the sex who have sought the "bad eminence" of being her imitators at the risk of sharing her infamy in the Penitentiary on Blackwell's Island, we have heard but little of female physicians in New York until recently. A more respectable instance is now announced in the case of a lady who has been before the public as a lecturer upon anatomy, physiology, &c., for some years, who has come out in favour of the water cure, and has recently taken to herself a husband, and they twain are conducting a hydropathic establishment, which, under their joint direction, is prepared to pack ladies and gentlemen in wet sheets or blankets, give them the cold or hot douche, sitz bath, &c.; pledging themselves to use no drugs except in the microscopic quantities which are found in the unfiltered croton. We should not marvel if this should turn out to be a popular move in the right direction, seeing that "there is a lady in the case."—*New York Med. Gaz.*

ON THE MORTALITY PRODUCED BY CHOLERA IN THE INDIAN ARMIES. ACCORDING to Dr. Finch, during the prevalence of cholera in India in the year

1847, our armies did not suffer so severely as it is commonly supposed. This is shown by the following table :—

	Number of men.	Attacked by cholera per cent.	Deaths from cholera per cent.
Madras Presidency.	11,429	0.271 (1 man in 500)	0.192 (less than 1 in 500)
Bombay Presidency.	8,756	0.515 (1 man in 200)	0.274 (1 man in 400)

The Native Army appears to be attacked in nearly the same proportion :—

Madras Native Army.	67,850	0.384 (1 man in 300)	0.114 (1 man in 900)
Bombay Native Army.	42,980	0.575 (1 man in 200)	0.227 (1 man in 400)

These results show that the risk of life from the endemic cholera of India is not so great as it is commonly believed to be.

THE CHOLERA AT TUNIS.

LETTERS from Tunis announce that the cholera had begun to cease its ravages ; for the number of deaths, which on the 16th ult. were forty-eight, had fallen to four on the 1st inst.

LOW TEMPERATURE SUSTAINED BY HUMAN BEINGS.

It is stated by Mr. Rae, in his Narrative of the Arctic Expedition, 1846-7, that at Fort Hope, in latitude $66^{\circ} 32'$, and longitude $86^{\circ} 55'$, the lowest temperature experienced during the winter was -47° . This is equal to 79° below the freezing point of water, and 7° below the freezing point of mercury.

A SNAKE STORY—EXTRAORDINARY OPERATION.

THE astonishment of the community has been excited by the report of a most wonderful and extraordinary operation having been performed by some two or three *medical gentlemen* of this city, upon a woman labouring under some supposed obscure abdominal disease. The report has it, that two serpents, or eels, were taken from the stomach or a sac in the peritoneal cavity, and they are actually exhibited *without charge* (preserved in spirits) to any one wishing to see them, at an apothecary store in the vicinity of Broad Street. We understand that *thousands* have already availed themselves of the privilege, many going away satisfied that they have seen the *elephant*, while others are willing to pay the most devoted reverence at the shrine of surgical art. The bold operators are being emphatically lionized ; and certainly nothing could have been more auspicious for an aspirant for medical fame and practice, than the occurrence of such a wonderful phenomenon. We are inclined thus much

to discourse upon the subject by evidence from a reliable source that certain individuals had seen the doctor who performed the operation, and that the doctor, in answer to the many inquiries put to him about the diagnosis and operation, distinctly told the crowd that, by the use of the stethoscope and speculum, and about twenty other instruments, the thing was accomplished. But the richest part of the story is, that the operation lasted one hour and a quarter, on account, it is said, of one of the monsters having his tail coiled around the liver, and its being extricated with much difficulty !—*Boston Medical Journal*.

FLUORINE IN BLOOD AND MILK.

DR. G. WILSON was the first to announce that fluoride of calcium was soluble in water, and that it existed in many natural waters. He states that 16 fluid-ounces, or 7000 grains, of water at 60° hold dissolved 0.28 grs. of fluor spar. This is in the very large proportion of two and a half grains to the imperial gallon : hence, if there be no mistake in the results, it follows that some natural waters contain more fluoride of calcium than sulphate of lime !

In pursuing his investigations, Dr. G. Wilson has recently examined the fresh-drawn blood of the ox ; and in the experiment he employed 26 imperial pints, or $3\frac{1}{2}$ gallons of blood. The mode in which the analysis was performed is not described ; but the analyst states that the evidence in favour of the presence of fluorine in the blood of the ox seems unexceptionable : and it cannot be doubted that the blood of other animals will be found to contain the same element. The fluorine was supposed to be in the state of fluoride of calcium ; but the amount was so small that no quantitative estimate was made.

Nine imperial pints (rather more than a gallon) of rich milk were examined, and the vapour which they evolved etched glass distinctly. The ashes of twelve pounds of new skim-milk cheese, treated in the same way, occasioned deep etching of glass. Dr. W. thinks that, as in other cases, the fluoride of calcium is associated with phosphate of lime, and that when milk is coagulated it separates with the caseine.

* * Hitherto chemists have found fluoride of calcium as a constituent of the body in the teeth, bones, and, according to some, in the urine. Its presence in the teeth rests upon the authority of Berzelius. Dr. Wilson admits that, notwithstanding the enormous quantities of blood and milk used by him, the proofs of the presence of fluoride of calcium were not so decisive as he could have wished. We think further experiments are required before the fluoride can be considered as a constituent of these animal liquids. It is a remarkable fact that the fluoride of calcium is generally associated with phosphate of lime in the mineral kingdom: and while barely a trace of fluoride is found in recent bones, it is very abundant as a constituent of the fossilized bones of extinct animals. Is there any conversion of phosphate to fluoride of lime yet unrecognized by chemists?

PHOSPHORESCENCE OF POTASSIUM.

At the recent meeting of the British Association, it was stated by Mr. Petrie, that when cold potassium was cut in the dark, he found the two cut surfaces to be distinctly luminous, although the luminosity was much less than that of phosphorus under the same circumstances. This evolution of light probably arises from rapid oxidation. So soon as the metallic surface is covered with a layer of oxide of potassium the phenomena of phosphorescence ceases.

QUACKERY IN AND OUT OF THE PROFESSION.

We quote the following from our new transatlantic contemporary, the *New York Medical Gazette*. It is too much the custom to apply the term quack to those only who happen to have no license or diploma; but this is a perversion of the real meaning of the word.

"The term quack is properly applied to an ignorant or unprincipled practitioner of the healing art, and to such only. He who dares to give remedies, of which he knows little, in diseases of which he knows less, and applies them to living beings, of whose structure or functions he knows nothing, is demonstrably a quack by reason of his ignorance and temerity; while he who imposes upon the public by seeming to be what he is not, and who, for the sake of

filthy lucre, sacrifices principle, honesty, and conscience, in the sale of nostrums or specifics, promising to cure incurable diseases, and exacting extortionate fees from the afflicted, by taking advantage of their ignorance or credulity,—is a quack because he is unprincipled. Such knaves abound in the profession, and they are such whether with or without diplomas, and to whatever school they belong; they are all alike,—whether called allopathists, homoeopaths, or chrono-thermalists; and whether they employ mineral, botanical, electrical, galvanic, magnetic, or metaphysical remedies. Their ignorance and unprincipled conduct constitute them quacks; and to protect the public from being plundered and victimised by such, is the only and all-sufficient reason for the warnings against quackery which the regular profession are ever reiterating through the public press. That these warnings are to a great extent unheeded, is the chief cause of the great mortality, especially in the large cities, where ignorant and unprincipled physicians abound, and where they find their most numerous victims."

REPORT OF THE MEDICAL BENEVOLENT FUND FOR THE YEAR 1849-50.

REMARKABLE as was the history of the last year in the development of their resources, and in the increased demand upon those resources, yet the Committee observe, that the year just concluded has in both instances exceeded its predecessor; for the amount received in subscriptions for the last year has been £490. 17s. 3d., and the sum granted in benevolent aid has been £439, distributed among forty-five cases of distress.

It will be seen that the former has exceeded the amount of last year's subscriptions by £74. 2s. 1d. notwithstanding that death has been unusually rife among the subscribers;—and that this fact, added to the pressure of the times upon professional income, has occasioned many subscriptions to be lost to the fund; and, notwithstanding this other fact, that some subscriptions have been this year omitted, in consequence of the parties having given donations to the special fund,—a consequence which your Committee had last year foreseen and deprecated. Your Committee are pleased to record, that these instances have been few; but, although few, they have had a certain influence upon the amount of your income. It is with real pleasure, however, they announce the accession of a considerable number of new subscribers, and the augmented subscriptions of many old ones.

Your Committee beg to call your attention to the circumstance, that while the number of cases relieved this year has ex-

ceeded that of the former year in the proportion of forty-five to thirty-four, the sum expended in benevolent aid has been less by £15. 4s. This has not arisen from the cases being less pressing or urgent, but from the smallness of their resources: they have been often obliged to vote £5, when their judgment and their feelings would have dictated a much larger sum; but under their inability to give more, they rejoice to say that their grants have been most thankfully received, and have been productive of the most signal benefit; in no preceding year has the amount of distress relieved been so great.

There have been cases which your Committee have been compelled to dismiss without relief, upon their own demerits; but there have been others which they have been obliged to dismiss without aid, simply because they had no funds from which to give. They also beg to state that they have experienced considerable embarrassment in the past year, from the irregular or tardy payment of subscriptions; and that had it not been for the kindness of their Treasurer, many of the cases must have been postponed at a time when present aid was of the utmost importance. They therefore beg to impress upon the subscribers generally, and upon their local Secretaries particularly, the great value of regularity of payment at the commencement of each half-year.

Your Committee took occasion, in their last Report, to urge upon you the importance of special donations, in order to bring the Donation Fund into action. An appeal upon this subject was circulated, and has been responded to in a way which has exceeded their most sanguine expectations. Your Committee had certainly hoped that they should by this measure bring up the Donation Fund to the sum required by your constitution—viz., £3,000; and they have much pleasure in informing you that it has reached £2,179. 10s. 6d.

Your Committee deeply feel that each one of their generous donors is entitled to their best thanks for the aid thus afforded; and they venture to hope that in the majority of instances this countenance may be continued in the shape of some annual contribution: the pressing demands for more income to their subscription fund will be seen by a consideration of the cases appended to their printed statement; and it is only by enlarged annual subscriptions that the prosperity of your institution can be secured and increased.

Your Committee congratulate you upon the origin, during the past year, of a Provident Institution for medical men and their families, upon just and safe principles: and to those who possess the means,

they earnestly recommend this method of providing against old age and infirmity, as well as for widows and orphans, and other calculable contingencies. A benevolent branch is attached to this fund for the relief of its members, who may fall into difficulties,—a provision which can in no way interfere with your fund, though in process of time it may serve to diminish the number of dependants upon it,—a consumption most devoutly to be wished, when it is considered how great are the demands upon your resources,—how inadequate are your resources to those demands,—and the high probability, that as your purely charitable agency is more widely known, a greater amount of professional misery will be detected. Nor can it be hoped, that even in the event of the new provident fund being eminently successful, it can ever supersede, or indeed materially diminish the necessity for your own simply benevolent institution. Your Committee, therefore, earnestly entreat you to strengthen their hands, and to extend the influence of the only purely charitable fund in England.

Your Committee have the pleasure to inform you that steps have been taken to bring their donation fund into action on the first of November next; though prudence has compelled them to suspend for the present, until more prosperous days, the granting loans to medical men for a given time without interest.

Your Committee beg your attention to their financial statement, by which it will be seen that their balance in hand is reduced to £33. 1s. 1d. and it is only by renewed efforts, especially to promote subscriptions, that they can in any way hope to relieve those who are now waiting for assistance, and to meet the misery which is so continually brought before their notice.

Your Committee beg your attention to some partial changes which they have felt called upon to make, and which they trust you will sanction with your approbation.

In consequence of some persons mistaking the object of your fund, and believing that its operation was confined to the provinces, your Committee have deemed it necessary to declare its purely catholic nature—and to designate it, as indeed it is in truth, "The Medical Benevolent Fund."

And in consequence of the illness of Dr. Baron, the removal of Dr. Conolly, and from the circumstances of Cheltenham, as well as of the increasing importance of the metropolis, both in the amount of subscriptions, and the number of cases relieved,—it has been thought advisable to remove the meetings of the Committee to London, and to associate with the old members fifteen gentlemen chosen from subscribers in the metropolis. They are

happy to inform you that Dr. Baron, as President, will continue to take the same interest in the welfare of the Society which he has felt from its foundation; and that Dr. William Conolly will also still act as Secretary to the Committee, and correspond, as he has previously done, with the Treasurer, Mr. Newnham.

Your Committee have farther to report, that they have maturely considered various propositions which have been placed before them for the extension of their body, in order to give a broader hold upon the affections of the many for their fund; and to interest a greater number of individuals in the cases to be relieved; and they have resolved upon giving a seat at the Committee-table, with the privilege of voting, to the President of the Council, the President of the Association, the President of each Branch of the Association, for the time being, and to each Local Secretary of the Benevolent Fund; thus securing that representative system in their operations which has been, by some, thought so desirable.

Your Committee assure you, that they will ever give their best attention to every proposition which may be made to them for the improvement of the fund, though they must reserve to themselves the right of their own unbiassed judgment; and will ever unflinchingly act upon their convictions, uninfluenced by the smiles of approbation or the frowns of displeasure.

A comparative view of the progress of your Institution has been also this year added to this report, as well as a separate list of all donors of £5 and upwards, *previously to the 1st of July, 1847.*

Your Committee would not quit this part of their report without earnestly recommending to your notice and kind feelings, the adoption of an after-dinner collection, at each one of your anniversary dinners, and also of your branches; thus assimilating yourselves with almost all the leading charities of the day, and securing aid for the relief of those who have no means of festive enjoyment.

Your Committee beg to express their deep sense of gratitude to their non-professional donors and subscribers; and to breathe their earnest hope that their contributions may be twice blessed.

Also your Committee are anxious thus publicly to record their thankfulness to the "Medical and Legal," the "Eagle and Protector," and the "Crown" Life Assurance Offices, for their generous donations towards their common object.

Again your Committee desire emphatically to offer the tribute of their thanks to the Editors of the *Lancet*, the *Medical Times*, the *Provincial Medical and Sur-*

gical Journal, and the *Medical Directory*,* for their respective kindness in assisting the extension of the knowledge of your Institution.

Your Committee have long felt the importance of possessing a London banker to whom, and through whom, subscriptions might be paid; and they have much pleasure in informing you, that this advantage has been obtained in the firm of *Herries, Farquhar, and Co.*

Your Committee are not aware that further motives can be required for activity and energy in a cause so pure, so benevolent, so heavenly. But they are unwilling to take leave of you for another year, without humbly avowing their deep sense of gratitude to the Giver of all good, for the measure of success which has attended their efforts; and without inscribing upon their pages, the words of the great Author of Benevolence, "Inasmuch as ye have done it unto one of the least of these, my brethren, ye have done it unto me."

JOHN BARON, M.D. F.R.S.,
President.

W. NEWNHAM,
Treasurer and Hon. Sec.

DEGREES GRANTED BY THE UNIVERSITY OF GLASGOW.

THE Senate of the University of Glasgow, at their meeting on the 7th inst., conferred the Degree of M.D. on the following gentlemen:—John Coombe Maddever, England; George Lade, Scotland; George M'Gillivray, Scotland; John Grieve, Scotland; James Brash, Scotland; James M'Collum, Ireland; James March Craig, Scotland; and the Degree of C.M. on Dr. John Coombe Maddever.

APOTHECARIES' HALL.

NAMES of gentlemen who passed their examination in the science and practice of medicine, and received certificates to practise, on Thursday, 22d August, 1850:—John Rigby, Preston, Lancashire—Charles Anderson Dalgairns, Guernsey—Claudius Galen Wheelhouse, Leeds—James Hurdie Black, Dysart, Fife, N.B.

OBITUARY.

On the 16th inst., at his residence, 2, Priory Parade, Chesham, James Williamson, Esq., M.D., late H. E. I. O. Bengal Service, in the 82d year of his age.

* We shall be glad if Dr. Baron or Mr. Newnham will inform us why the *London Medical Gazette* has been excluded from this list. The interests of the Benevolent Fund have always been advocated in our pages.

CASE OF MELANOSIS OF THE EYE.

BY DR. BETHUNE.

THE patient, a healthy farmer, sixty-five of age, entered the Eye and Ear Infirmary under his care. Twenty years ago, he first observed a red spot at the outer angle of the left eye, wedge-shaped, and with the apex towards the pupil, as in pterygium. For fifteen years it was stationary; but five years ago it began to grow, and at the end of one year he was only able to discern the light. Pain came on, when the disease began to increase, and was severe for the first two years; it was then less again till last autumn, since which time it has increased, being occasionally severe and darting, and at times dull and heavy.

On examination, the right eye is well. Lid of left eye separated by a black, smooth, but irregular mass, projecting from the anterior third of the ball, and compared to a peach-nut with the base outward and the anterior half cut off. A few days after his admission the eye was removed, and at the end of a week the parts were healing well, and he was discharged. The eye seems to be healthy, except for the tumor, which does not invade the internal parts.

Under the microscope, Dr. H. J. Bigelow had observed the following appearances: "First, numerous cells, apparently epithelial; secondly, numerous cells, of irregular outline, enlarged by a power of five hundred diameters to the size of a five cent piece, and containing sub-cells and nuclei; also some of a marked caudate figure. These, with others decreasing to simple nucleated cells, with one or two nuclei, the diameter of which cells was only three or four times that of blood corpuscles, were probably cancerous. And to account for the black colour the whole field was filled with granules, often aggregated into masses resembling Gluge's granulation cells; which last, however, may have been the product of independent inflammation."—*American Journal of the Medical Sciences*, July 1860.

REMARKS.—The total number of deaths was 139 below the average mortality of the 24th week of ten previous years.

NOTICES TO CORRESPONDENTS.

Mr. Herbert Williams.—The report has been received: it shall have our immediate attention.

Mr. Hunter's additional paper has come to hand, but too late for the proposed addition.

The letter of Mr. Henry Smith, the Hospital report of Dr. Barclay, and the Memorial of the Manchester Ethical Association, will be published in the next number.

Communications have been received from Mr. D. (I. Edwards—Dr. Nevins—and Mr. W. Smith, of Belper. To the latter, a private note will be sent.

RECEIVED.—The Dorset County Chronicle.

Mr. R. J. A., Neath.—Dr. Canning, of Edinburgh, has written to inform us, in answer to the question addressed to him by this correspondent, that, in the cases referred to, the tar is usually administered in the form of Capsule (similar to the Carter's Oil or Cod-liver Capsules), one thrice a-day on the average. The Capsules are generally sold by the box, and can easily be procured either in London or Edinburgh.

Not unfrequently an eruption, like that of scarlet fever, follows their use. I always inform the patients of this, as they are apt to become alarmed by its appearance.

ERRATA.—In Mr. Bate's Notes on the Teeth, in the last number, page 328, under Fig. 2, for "tubular structure of loop," read "tubular structure of dentine."—P. 330, under Fig. 4, for "malbecius," read "merluccius."—P. 332, col. 2, line 25, for "is," read "are;" and l. 40, for "formed," read "found."—Page 333, l. 1 (of text), for "soda," read "lime."

Lecturers.

COURSE OF LECTURES

ON

DISEASES OF THE HEART.

Delivered at St. Vincent's Hospital during the Session 1849-50.

By O'BRYEN BELLINGHAM, M.D.

Fellow of, and Member of the Court of Examiners of, the Royal College of Surgeons in Ireland, and one of the Medical Officers of the Hospital.

LECTURE XI.

EXAMINATION OF THE HEART IN DISEASE, CONTINUED.

Abnormal sounds developed during the heart's action—Sawing, filing, and grating valvular murmurs—Conclusions from the presence of a rough valvular murmur—Musical valvular murmurs—Arterial murmurs—Arterial bruit de soufflet—Rough or grating arterial murmurs—Venous murmurs—Continuous venous murmur—Musical venous murmur—Seat of the continuous and musical murmurs—Mechanism by which they are produced.

Sawing, Filing, and Grating Valvular murmurs.

THE valvular or endocardial murmurs next to be considered have a harsh, rough, or grating character: they were first described by Laennec, and have received various names: as the "sawing murmur" (bruit de scie); the "rasping or grating murmur" (bruit de râpe); and the "filing murmur" (bruit de lime); which more or less resemble these familiar sounds. Although the rough valvular murmurs are distinguished by different names, they are by no means to be regarded as characteristic of distinct forms of disease;—in fact, they are nothing more than degrees or varieties of rough sounds, having the same origin as bruit de soufflet, although less common than it, and more decidedly pathognomonic of organic disease of the valves or orifices of the heart.

It is a common opinion that the harsh grating valvular murmurs are the result of osseous or calcareous degeneration of the valve at which they have their seat, and that they always indicate a more advanced state of disease of the valves, or a greater amount of contraction of the orifice than bruit de soufflet. This was the opinion of

Laennec, and thus appears to be the view taken by M. Bouillaud; it is far, however, from being correct: these sounds are heard in cases where the valves have undergone neither calcareous or osseous degeneration; and a very advanced state of disease of a valve is often indicated simply by bruit de soufflet, while, in the most advanced stage of all, it may disappear, and no murmur of any kind be audible. This is sometimes witnessed at the mitral orifice, when the contraction becomes so extreme as not to permit a sufficient current of reflux blood through it to develop a murmur.

Although these harsh grating sounds do not necessarily indicate either osseous or cartilaginous degeneration of the valves, and are often not heard in cases where valvular disease is much advanced; yet, when they are well marked, we may conclude that the degree of friction between the blood and the parietes of the orifice at which they are developed, is greater than where simply bruit de soufflet is heard. In the majority of cases this is owing to hypertrophy, or hypertrophy with some dilatation of the ventricle complicating the valvular disease, by which the contractile power of the ventricle is increased, and the blood is transmitted with augmented force through the diseased orifice. Hence the rough valvular murmurs are limited in a great measure to the period of the ventricular systole and the first sound of the heart, and are not heard in inorganic affections of the organ, in which bruit de soufflet is so common.

In almost every instance the rough grating murmurs are preceded by bruit de soufflet; the one insensibly passes into the other; and the former are to be regarded as merely more intense degrees of the latter. For instance, when, owing to disease of the semilunar valves of the aorta, or of the aortic orifice itself, the passage outwards of the blood is obstructed, a bruit de soufflet will be developed: if the impediment increases, owing to increase of the obstruction,—and if, as usually occurs, the parietes of the left ventricle become hypertrophied,—the bruit de soufflet will pass into a sawing, filing, or rasping murmur. On the other hand, when the aortic valves merely permit regurgitation, no increase of the disease will convert the bruit de soufflet into a rough or grating murmur,—because the force with which the current of blood enters the ventricle is never sufficiently great to develop a harsher sound than bruit de soufflet. The rough grating valvular murmurs are consequently limited to the period of the ventricular systole; they replace only the first sound of the heart, and are, in a great measure, limited to disease of the aortic orifice or its valves.

Conclusions from the presence of a Rough Valvular Murmur.

1. The sawing, filing, grating and valvular murmurs are to be regarded as nothing more than bruit de soufflet exaggerated.
2. They are limited to the period of the first sound of the heart, and accompany only the systole of the left ventricle.
3. They are heard only in cases of organic disease of the valves or orifices.
4. The diseased state in which they are most generally audible is narrowing of the aortic orifices.
5. In almost every instance hypertrophy, with dilatation of the left ventricle, accompanies the valvular disease.
6. The sawing, filing, and grating valvular murmurs do not necessarily indicate either osseous, calcareous, or cartilaginous degeneration of the valves or orifices.

Musical Valvular Murmur.

The musical murmur of the heart—the "bruit de soufflet musical ou sibilant" of the French writers—is a very remarkable and rather rare sound: it resembles sometimes, as the name denotes, a whistle; sometimes the notes of a wind instrument; at others, the chirping of a bird, or the whining of a puppy; and at others, the cooing of a dove, or the mewing of a kitten. It may consist of only a single note, or of two or three; seldom more: it is sometimes so loud as to be audible without the stethoscope, and at some distance from the patient; and it may accompany either the systole or diastole of the ventricle.

We are indebted to Dr. Elliottson* for the earliest description of this murmur: he first called attention to it as a sign of valvular disease, and described the particular lesion of the valve in which he had met with it. Laennec says he never heard a musical murmur in the heart, but he has described a musical murmur of the arteries: the latter, however, we know now has its seat in the veins, not the arteries.

The musical valvular murmur is to be regarded as nothing more than a variety of bruit de soufflet, which almost always precedes it, and usually takes its place when it intermits or subsides, or when the exciting cause has been removed. In fact, as both Dr. Hope and M. Bouillaud remark, "there is no greater difference between the two sounds than there is between blowing with the lips, and whistling." Thus, in a case which was in hospital some time since, a loud musical murmur was heard upon the day of the patient's admission, after the exertion of walking to the hospital. On the day following, when the

circulation had become more tranquil, this murmur had disappeared, and was replaced by bruit de soufflet. On a post-mortem examination some time subsequently, the valvular lesion was found to consist in a cribriform condition of the curtains of the mitral valve, by which regurgitation had been permitted. In a case of acute endocarditis, which was in hospital a short time since, the bruit de soufflet was first heard; and when the patient had been submitted to treatment for a short time, this was replaced by a musical murmur, which continued to be audible as long as the patient remained under observation.

Like the sawing, rasping, filing, and other rough valvular murmurs, the musical murmur is almost always a sign of organic lesion of one of the valves or orifices of the left side of the heart; and, so far as I have had the opportunity of observing, it is almost limited to the regurgitant lesions of the aortic and mitral valves. This murmur is frequently accompanied by fremitus cataire, and may be audible in any case in which the semilunar or the mitral valves imperfectly fulfil their functions, provided the aperture through which regurgitation occurs is small, and that the heart acts vigorously.

As regurgitation cannot occur in a healthy condition of the valves, and as the musical murmur is in a great measure limited to cases of regurgitation, it is a valuable physical sign, when present, of valvular disease; and it may be regarded as almost pathognomonic, if combined with other symptoms of organic disease of the heart.

The division of abnormal sounds, which we have next to consider, have their seat in the arteries or in their veins, or in both. They all, with one exception, come under the head of what are called "*inorganic murmurs*." They are—

1. The arterial bruit de soufflet.
2. The rough grating arterial murmur.
3. The continuous venous murmur, or "bruit de diable."
4. The musical venous murmur.

Arterial Murmurs.

The abnormal sounds which have their seat in the arteries may, like those developed at the orifices of the heart, have either a blowing or a rough grating character. It is only in the large arteries that they are heard; and in investigating them it is always necessary to employ the stethoscope,—indeed, M. Vernois has proposed a modification of this instrument for the sole purpose of examining the arteries, which consists in "excavating the two opposite points of its circumference for the reception of the vessels subjected to examination," by which the pressure upon the artery

* Lathamian Lectures.

caused by the stethoscopes ordinarily employed will be obviated. This appears to be an unnecessary refinement, as the instruments in common use are quite sufficient for every purpose.

Arterial Bruit de Soufflet:

The abnormal sound heard most frequently in the arteries is bruit de soufflet. In a state of health, the blood, in its passage through the large arteries, causes such slight friction that very little sound is produced: this is short, single, and repeated at equal intervals, from sixty to eighty times in a minute, and is synchronous with the ventricular systole, and with the pulse. If slight pressure be made upon the vessel with the finger, or with the stethoscope, this sound increases in intensity; and, if the pressure be increased, it is converted into a murmur having the character of bruit de soufflet. Increase of friction between the blood and the lining membrane of a healthy vessel, produced by merely diminishing the channel through which the current flows, is therefore sufficient to produce a murmur in a large artery.

Again, one of the most important properties of the blood is its viscosity. In some morbid conditions of the system this property is impaired; the blood becomes impoverished, attenuated, and watery; the red globules diminish; serum superabounds; and, as a natural consequence, the viscosity of this fluid is less than natural. In other cases the actual amount of blood in the system is diminished, as after profuse hæmorrhage, or when venesection has been carried to an extreme degree. In both these cases, the amount of friction between the blood and the lining membrane of the arteries must necessarily be greater than natural; and this increased friction is capable of developing a murmur analogous to the bruit de soufflet produced by pressure upon a healthy vessel. In order that the murmur be well marked, it is necessary that a certain degree of velocity of the current above the natural standard should occur in addition.

The arteries in which bruit de soufflet is most commonly heard are the aorta, the carotids and subclavians, the iliac and femoral arteries. It may be heard in any one, or in all these vessels, when the blood is propelled with increased force and velocity through them; or when the calibre of the artery is diminished by pressure from without; or when the coats of the arteries have lost their natural and healthy state of tension; or when the blood is more or less attenuated, owing to its watery parts being increased, and the red globules diminished,—the result either of profuse hæmorrhage, or of a chlorotic state of the

system. The latter are frequently accompanied by the abnormal sounds (presently to be described) which have their seat in the veins; in these, also, the action of the heart is more rapid than natural; and the arterial bruit de soufflet is sometimes accompanied by a murmur at the aortic orifice, depending upon the same cause.

The bruit de soufflet, which has its seat in the large arteries, has been mistaken for a valvular murmur, particularly when it has its seat in the arch of the aorta, or in the carotid and subclavian arteries. It may almost always be distinguished,—

1. By its character, which, as Dr. Hope observes, is "usually a mere whiff."
2. By its never being heard at the period of the ventricular diastole, and the second sound of the heart.
3. By its being usually audible over several arteries at the same time.
4. By the facility with which the murmur is altered by varying the amount of pressure of the stethoscope, by which it is converted into a hissing, or harsh murmur.
5. By its not being constantly present: by its subsiding occasionally when the circulation becomes tranquil, and returning when palpitation ensues.
6. By the general signs of anæmia being present.
7. By the absence of the physical or general signs of organic disease of the heart.
8. By its entirely disappearing under treatment calculated to relieve the anæmic state of the system.

Rough or Grating Arterial Murmurs.

It is a very general opinion that bruit de soufflet is the only abnormal murmur developed in the large arteries. This, however, is far from being the case: a rough, harsh, or grating murmur, is not infrequent, but its seat is limited in a great measure to the arch of the aorta, and it is not confined to the period of the ventricular systole, but frequently accompanies the ventricular diastole likewise. It is probably owing to these circumstances that the phenomenon has been overlooked, the murmur, when heard, having been confounded with a cardiac murmur.

In a healthy state of the arterial system, the arteries, we know, are constantly full; when the amount of blood transmitted to them is increased, the artery dilates, in order to accommodate itself to the increased quantity; when the amount of blood is diminished, the arterial coats contract upon their contents, and the calibre of the artery is diminished in proportion; but, whether the amount of blood is greater or less, these vessels are always full. This depends upon the peculiar property possessed by arterial tissue, usually termed elasticity,

but which is evidently something more than mere elasticity, which is a property common to dead as well as living tissues. The aorta in a healthy state possesses this peculiar vital property in a high degree; which is due not only to its proper fibrous coat, but to its suberous or *sclerous* coat, which in this artery is very well developed, as described by Dr. Norman Chevers.*

It not unfrequently happens that the coats of the arch of the aorta suffer from disease, which impairs its elasticity; the tube becomes rigid, and its calibre cannot alter with the increased or diminished amount of blood transmitted to it. At the same time, the natural smoothness and polish which its lining membrane presents in the healthy state is diminished; or, the interior of the artery becomes rough and uneven from adventitious deposit; while very generally its calibre becomes somewhat increased.

During the systole of the left ventricle the arch of the aorta is necessarily more distended than during the ventricular diastole: in the morbid condition under consideration, however, as its coats are incapable of contracting upon their contents, and as the calibre of this part of the vessel remains the same at these different periods of the heart's action, a vacuum would occur here when the ventricular systole ceases, but that the blood regurgitates from the carotid and subclavian arteries to occupy it; and this can scarcely occur without producing sound, which will, of course, accompany the ventricular diastole, and the second sound of the heart.

In this diseased state of the arch of the aorta, not only is the artery rigid and inelastic, but often its interior, owing to adventitious deposit, becomes uneven and rough; there will therefore necessarily be increased friction between the blood and the lining membrane of the vessel, and a murmur will be developed, which will be heard at the period of the ventricular systole, and will be synchronous with the first sound of the heart, and with the pulse. As the ventricular systole ceases, the blood from the large vessels which come off from the arch of the aorta regurgitates into this vessel, and the passage backwards of this fluid over a similar rough surface causes a second murmur, which will, of course, be synchronous with the ventricular diastole, and the second sound of the heart.

When the stethoscope is applied over the first bone of the sternum in this diseased state of the arch of the aorta, a short, double, rough, harsh murmur, will be heard, loudest over the first bone of the sternum, and audibly frequently as low as the base of

the heart, sometimes a little lower down, but never at the apex of the organ. The first of these sounds is synchronous with the ventricular systole, and the pulse; the second, with the ventricular diastole. Both sounds appear to be near, and both are short and rough, not either prolonged or blowing. In some instances a murmur is present only with the first sound, or even this may be absent, and the second sound may be neither rough or harsh. This will occur when the arch of the aorta, although rigid and inelastic, has not lost, in any great degree, its natural smoothness and polish, but still permits regurgitation into it: the double sound then heard resembles very closely the double sound of the heart, and is commonly supposed to be transmitted beyond its normal limits. It may even happen that the arch of the aorta is dilated, rigid, and inelastic, and its lining rough and irregular, and yet no murmur will be developed: this will occur when the heart's action is feeble from softening or other alteration of the muscular tissue of the left ventricle, or when the arterial system is congested; or when the cavities of the left side of the heart are overloaded, or over-distended with blood. Under similar circumstances we know that a murmur may be absent in cases of considerable disease of the valves or orifices of the heart.

In addition to the physical signs above mentioned, this diseased state of the arch of the aorta is accompanied by the peculiar jarring of the pulse which was supposed to be characteristic of regurgitation through the aortic valves; by strong and visible pulsation of the carotids; and by a visible and locomotive pulse in the arteries of the upper extremities. The peculiar jerking of the pulse, and the visible and locomotive pulsation of the arteries, depend upon the same cause as where the aortic valves permit regurgitation: here, however, the regurgitation is into the aorta itself. These signs will be more marked if the arch of the aorta, in addition to being rigid and inelastic, is at the same time dilated, and, if the action of the heart is strong.

The physical signs of this diseased state of the arch of the aorta have been hitherto supposed to be referable to valvular disease of the aortic orifice: no writer that I am acquainted with seems to have been aware, that regurgitation into the arch of the aorta, from the larger vessels which come off from it, ever occurs, or that a backward current of blood in this part is capable of developing a murmur. This has probably arisen from the general symptoms, in the early stage, not being such as to attract particular attention; and, as patency of the aortic valves is one of the consequences of the long continuance of this diseased

* Guy's Hospital Reports.

state of the aorta, when the latter lesion has been found after death, the symptoms have been always referred to it.

The form of cardiac disease with which this diseased condition of the coats of the arch of the aorta has been most frequently confounded, is a state of the aortic valves permitting regurgitation, which it resembles in a murmur, synchronous with the second cardiac sound, accompanying both morbid conditions, in the jarring pulse, and the visible pulsation in the arteries of the neck and upper extremities, which are common to both. It may always, however, be distinguished by the character of the murmur with the second sound, which, in this diseased state of the aorta, is short, rough, and harsh, while in patency of the aortic valves it is always prolonged, soft, and blowing; as well as by the situation in which the murmur is transmitted to the ear: in patency of the aortic valves it is audible from the base to the apex of the heart: in this morbid condition it is loudest over the first bone of the sternum, and it is not heard below the base of the heart; at least, it is very indistinct below this point. Besides, in this diseased state, when a murmur accompanies the second sound, one is likewise always heard with the first, which is not the case in simple patency of the semilunar valves.

Venous Murmurs.

The abnormal sounds, which have their seat in the veins, may have either a blowing or a musical character. They all come under the class "inorganic murmurs," and have received a variety of names; as the venous murmur, or venous hum, the sound of continuous blowing, bruit de soufflet continu ou à double courant, bruit de diable, and musical venous murmur, or melodious blowing sound. They may all be included under the heads, continuous, and musical venous murmur.

Continuous venous murmur.—The continuous venous murmur, or venous hum, is termed continuous from its being a continuous uninterrupted sound, and venous from its seat. M. Bouillaud named it "bruit de diable," from its resemblance to the familiar sound made in the spinning of a kind of humming-top, which is known under the popular name of *diable* in France, and this name has been very generally retained since. It resembles pretty accurately the sound heard when a large univalve shell is held close to the ear; it has been also compared to the noise of the sea upon a distant sand, when the tide is flowing, or to the hollow sound made by a large forge-bellows constantly worked, or to

the buzz produced by a number of people talking together in a large room; and it may be imitated, as Dr. Hope observes, "by forcing the breath in whispering a continuous *who*." It is often accompanied by the arterial bruit de soufflet, which appears to increase its intensity at each systole of the ventricle, and it often acquires increased loudness at each inspiration, owing to the expansion of the thorax, which allows the blood more rapidly to descend to the right side of the heart.

The veins in which the continuous murmur is heard, are the jugulars, particularly the internal jugular, and the veins which open them. The situation in which it is best marked is immediately above the clavicle; it is not audible close under the chin; it may often be heard at both sides of the neck, though usually it is more feeble upon one side, or it may be limited to one side; and, in my experience, it is both more frequent and more intense upon the right than the left side, though M. Bouillaud states that he most frequently finds it upon the left side. The more direct course of the veins upon the right side of the neck, to reach the *vena cava*, may account for its greater frequency upon the right than the left side. The position in which to place the patient, in order to hear this murmur, is the sitting or standing posture, with the face inclined slightly towards the opposite shoulder, and the chin somewhat elevated.

The continuous venous murmur sometimes subsides suddenly at the point where it was audible a few minutes previously; slight change of position of the patient's head will produce this effect, or will alter the character of the sound. This depends upon the pressure exercised on the vein by the parts lying over it, which varies with the motions of the head. M. Bouillaud says, that drawing the larynx towards the opposite side will diminish the murmur suddenly, or cause it to cease; it does so by putting the omo-hyoid muscle upon the stretch, by which the deep cervical fascia is rendered tense, and pressure is made upon the internal jugular vein. Altering the pressure of the stethoscope alters the character of this murmur in a remarkable manner, sometimes diminishing, sometimes considerably increasing its intensity, and rendering it hoarse, or converting it into a musical murmur: when pressure sufficient to obliterate the current through the vein is made, either with the edge of the stethoscope, or with the finger above, the murmur ceases altogether.

Musical venous murmur.—The musical venous murmur is less frequently heard

than the continuous murmur: it has, however, its seat in the same vessels, is audible in the same situation, and occurs in precisely the same kind of cases. It is seldom audible in the male, and like the continuous murmur is more frequently heard upon the right than the left side of the neck. Like the latter, also, it intermits, changes its character, or ceases from very trifling alterations in the position of the patient: it is always preceded by the continuous murmur, which takes its place when it subsides. In order to hear either murmur, it is essential to employ the stethoscope: and although it is sometimes audible on very gentle pressure by the stethoscope, it generally requires stronger pressure with the instrument than is sufficient to develop a continuous murmur.

The musical venous murmur sometimes resembles a whistle with the lips, or the prolonged whistling sound of a current of air through a key-hole; sometimes it is more like the chirping of a bird, the singing of a kettle, or the humming of a fly; it has been also compared to the resonance of a tuning fork, the sound of the Jew's harp, or the prolonged vibration of a metallic cord. It often consists of a single note, sometimes of two, more rarely of several distinct notes. The French writers, who place its seat in the arteries, term it the melodious blowing sound, or the chant of the arteries; and both Laennec's and Bouillaud's works contain a scale, in which they have endeavoured to represent by musical notes the melody or air heard in some cases.

The musical venous murmur appears to have the same relation to the continuous venous murmur as the musical murmur of valvular disease has to the bellows murmur; the one is preceded by, and passes into the other, and the former is to be regarded as nothing more than an exaggerated variety of the latter. There is, in fact, no greater difference in the nature of the sounds, and in the mode in which they are produced, than there is (Dr. Hope observes) "between blowing with the lips and whistling."

Seat of the continuous and musical murmurs.—The continuous and the musical venous murmurs were for a long time supposed to have their seat in the larger arteries which come off from the arch of the aorta: this was the opinion of Laennec, who first discovered them; and it has been advocated by almost every French writer from him, to M. Bouillaud, M.M. Barth and Roger, and M. Beau, the latest authorities upon the subject. The first to correct

this error was Dr. Ogier Ward,* he it was who first demonstrated that the veins, not the arteries, were the seat of these murmurs, and who first pointed out the distinguishing marks between the venous and the arterial murmur.

In many cases, the continuous or the musical venous murmur are accompanied by the arterial bruit de soufflet already described; they may always, however, be readily distinguished from each other: the arterial murmur is an intermittent sound, the venous a continuous sound; the arterial murmur is a short, whiffing sound, while the venous has a humming or whistling character.

That the continuous and the musical murmur have their seat in the veins is proved by their diminishing, or ceasing altogether, when pressure with the finger is made upon the vein above, or when the stethoscope is pressed firmly on it, so as to obliterate the current: the feeble bruit, which is still occasionally audible, comes from the small venous branches in the neighbourhood. M. Bouillaud, who places the seat of these murmurs in the arteries, observes that "pressure above the vessel with sufficient force to interrupt the current will cause a cessation of the murmur," which is quite true: but it is not quite as easy as M. Bouillaud seems to think, to "interrupt the current" in the carotid or subclavian arteries; the degree of pressure required would cause rather more pain than most patients would like to submit to often; while the moderate degree of pressure necessary to interrupt the venous murmur would, if it had its seat in the artery, render it louder, instead of interrupting it. In fact, the trifling pressure which is necessary to cause the cessation of these sounds is the best proof that they have their seat in the veins; and that they are not seated in the arteries is proved by the true arterial bruit de soufflet being very often heard at the same time; and, by its continuing to be audible when the venous murmurs have been checked by the pressure of the finger or of the stethoscope.

Mechanism of production of the continuous and musical venous murmurs.—In order to explain the mechanism by which these murmurs are produced, it will be necessary to premise a few remarks. In preceding lectures I have endeavoured to prove that every sound, whether normal or abnormal, developed in the heart or arteries, is produced by friction between the blood and the lining membrane of the part; that abnormal sounds are nothing more than

* LONDON MEDICAL GAZETTE.

exaggerated normal sounds, and that the character of the abnormal sounds will vary according to a variety of circumstances; as the roughness or smoothness of the lining membrane, the nature and amount of the obstruction to the current of blood, the rapidity and strength with which the blood is propelled, and the physical condition of the circulating fluid, particularly its density and viscosity.

In the cases in which the continuous or the musical murmur are heard, the organs of circulation are in a healthy state; but the blood is altered; its density is diminished, its watery parts are increased, and its viscosity is less than that of healthy blood, while the current is more rapid than in health—conditions sufficient to develop a murmur in the arteries; and accordingly the arterial bruit de soufflet is very generally audible in such cases. The current through the veins being naturally feeble, compared to that through the arteries, its coats being lax and readily distensible, no great amount of friction can occur between the blood and the lining membrane of these vessels, even though this fluid be altered in the way that I have mentioned. In order, therefore, that a murmur should be developed in a vein, the friction between the blood and its lining membrane must be *mechanically* increased.

The murmurs which we are considering have their seat essentially in the jugular veins; principally, I believe, in the internal jugulars. Now in order that friction sufficient to develop sound should take place between the blood and the lining membrane of these veins, it is necessary that the tissues covering them—viz. the skin, the platysma, and the cervical fascia, should be made tense; which is effected by turning the patient's head slightly towards the opposite shoulder, and by elevating the chin a little, by which a moderate degree of pressure is exercised upon these veins in their whole course in the neck, and they are placed in a favourable condition for the development of sound. If the stethoscope be now applied, its pressure will slightly diminish the calibre of the vein, the friction between the blood and the lining membrane of the vessel will be increased, and a murmur will be developed, which will of course have a continuous character, because the current through the vessel is continuous. If increased pressure be made by the stethoscope the character of the murmur will be altered; it will be rendered harsher, or hoarser, or converted into a whistle, or other musical murmur, as the case may be; while if the stethoscope is pressed still more strongly upon the vein, so as to obliterate the current, the murmur will instantly cease.

I am therefore of opinion that the continuous and musical murmur, unlike the cardiac and arterial murmurs, are not naturally present in the veins of the neck, but that they are mechanically produced by the pressure of the stethoscope, when the coats of the vein have been rendered tense, by putting the parts covering it upon the stretch, by which the friction between the blood and the lining membrane of the vessel is increased. Thus, if we completely relax the fascia and muscles of the neck, by making the patient incline the head forward, and then apply the stethoscope, the murmur will be inaudible, or scarcely heard; while if we turn the same patient's head slightly towards the opposite side, the murmur will be loudly heard, although the same degree of pressure is made by the stethoscope.

Again, the bruit de diable is described by writers as being often audible one day and inaudible the next, and as disappearing suddenly at a point where immediately previous it had been loud. Now if we examine the connections of the deep fascia of the neck with the sheath of the cervical vessels, and with the muscles, we will perceive that a very trifling alteration in the position of the patient's head will render this fascia tense, or the contrary: and we can easily understand, therefore, how the pressure of the stethoscope may, in one position of the patient, fail to develop the murmur, while in another position the same amount of pressure will render it loud.

The venous murmur (as has often been observed) diminishes or subsides when the face is turned quite round towards the opposite side. Now the effect of this position is to render tense both the cervical fascia and the muscles which cover the internal jugular, by which so much pressure is made upon the vein as greatly to diminish the current through it, when of course the murmur will either subside or become very feeble. The venous murmur is sometimes heard on both sides, sometimes only on one side, and is usually better marked upon the right than the left side. This is readily explained by the more direct course of the blood towards the heart on the right than the left side. When this murmur has been only heard on the left side, the French writers (who suppose the carotid artery to be its seat) are obliged to refer it then to "some irregular distribution of the left carotid artery, by which this vessel is rendered more *superficielle*." "We must allow (M. Beau observes) a large share to the anomalies so frequent in the arterial system."

The continuous murmur ceases or diminishes materially in the recumbent posture, and returns again in the sitting or erect

posture. This may be accounted for partly by the effect of gravity upon the circulation in the jugular vein, and partly owing to the rapidity of the circulation being greater in the erect or sitting than in the recumbent posture. In cases of anæmia, change of posture exercises a more remarkable influence upon the rapidity of the heart's action than in the healthy subject: and as rapidity of the circulation is one of the conditions necessary for the development of the venous murmur, it follows that it ought to be more evident in the erect or sitting than in the recumbent posture. Besides, in the recumbent posture the fascia of the neck is more or less relaxed, and the vein is placed in an unfavourable state for the development of sound.

The foregoing circumstances all render it probable that the venous murmur is developed in the way which I have stated: this view alone reconciles all the apparent anomalies connected with it. Indeed, the theories heretofore advanced fail to account for its presence or its absence under many circumstances; while the majority of these theories seem to be little better than hypotheses, the correctness of which would require to be demonstrated before they could be adduced to explain the mechanism by which the venous murmur is produced.

The arterial and the venous murmurs will be again alluded to when I come to speak of what are termed "inorganic affections." It is only necessary here to observe that these abnormal sounds are very common in chlorotic, anæmic, and hysterical females, and in individuals who have suffered considerable loss of blood; and they are heard in all cases where the blood is altered, its serous portion increased, and its viscosity lessened. We seldom or never examine a chlorotic subject in whom some of these sounds are not present, frequently upon both sides of the neck, but seldom so loud upon one as on the other. The more advanced the stage of anæmia, the more intense in general are the murmurs; and as the anæmic condition is relieved by medical treatment, the sounds diminish in intensity, and eventually, when the patient's health is completely restored, they disappear.

CHLOROFORM IN OBSTETRIC PRACTICE. BY A. P. KING, BOSTON, U.S.

CHLOROFORM, as an anæsthetic agent, is one of the most powerful, and therefore one of the most valuable of its class. It is not proper that it should, in so short a time after its introduction, receive its final doom. More is to be learned of its power—its *modus operandi*—before we can justly place

upon it a proper estimate. To say that chloroform should be administered at all times and under all circumstances where anæsthesia is desirable, or that it should never be used because harm has been the result of its improper administration, is equally foolhardy.

The point which I should raise is this—Should chloroform be used in the practice of obstetrics? I answer, Yes—because it is more agreeably and conveniently administered than most other articles of the same class, and because it relieves the patient of a vast deal of suffering, which, without the aid of some anæsthetic agent, would be almost intolerable. We know that women have given birth to children, for thousands of years, without it—that they have borne the sufferings of travail with a fortitude unknown to the other sex. But the fact that they always *have*, is not conclusive that they always *should*, suffer, so long as satisfactory demonstration has proved that the parturient couch can be made

"Soft as downy pillows are."

We are culpable for withholding anæsthetic agents, in the practice of obstetrics, when they can be safely administered, as we should be for refusing to prescribe for disease under similar circumstances. The only question in the minds of many is as to the safety of the patient while under its influence. The general rule is, I believe, the patient is safe: notwithstanding, the rule, like all other general rules, may have its exceptions.

Opium does not *always* produce stupor—ipecac. does not *always* produce emesis; yet the general rule is not yielded in consequence of these exceptions. So with chloroform. Owing to some idiosyncrasy, beyond our power to fathom, it does not always produce the same effect upon different constitutions. Yet enough has been learned of its effect (I had almost said *modus operandi*) to satisfy all but the overtimid that a judicious administration of chloroform is not only practicable, but desirable. That there are circumstances under which it should not be administered, I have no doubt: I have seen them.

It has been asked by some, if it does not interfere with the progress of labour. I can answer from experience in the affirmative, so far as the exceptions to the rule go—but in the negative generally. By generally, I mean that in a large proportion of cases the contractions of the uterus are not interfered with. Rarely, *very rarely*, does it retard labour. I am using it with most of my lying-in women, and as yet have seen no ill effects from its inhalation.—*Boston Med. Journal*.

AN ESSAY ON

UNHEALTHY INFLAMMATIONS.*

BY M. BROKE GALLWEY,

Assistant-Surgeon Royal Regiment of Artillery,
Woolwich, Kent.

EPISTELAS.†

THAT medicine continues to lie under the opprobrium of a lack of *settled principles*, and that her sisters—the “exact sciences”—refuse to acknowledge her as one of themselves, is due, I think, to nothing more ostensibly than to the disregard which the great truth, that “the life of the flesh is in the blood,”‡ has experienced at the hands of her disciples. The long reign of *solidism*, under which she has dragged “her slow length along,” has operated, I think, most injuriously to her interests, and kept her down in the struggle for existence. When the *humoral* aspect of disease began to lose its ascendancy, and to be remembered only as a creation of the distempered fancy of the ancients, when that crisis overtook her, it is not, I think, too sorrowful a tribute to its memory to say, in the language of the illustrious departed, “Sol occubuit; nox” longa “secuta est.” The luminous mind of Sydenham was exerted for a while with some success to arrest the downward course of humoralism, and to throw the protection of a great name around the peculiar offspring of our forefathers; to which end, however, it needed no less unequivocal a declaration than this, that “a disease, how adverse soever its cause may be to the human body, is nothing else but nature’s endeavour with all her

might to expel the morbid matter for the good of the patient.” That in this aphorism resides the essence of almost all that has yet been *made out* in the numerous family of the blood diseases, is a truth which the humoral tendency of the present day, I think, sufficiently attests. The primary import of the *blood* (wherein, as early as the days of Moses, we were admonished that “the life” resides), in the causation of disease, has been industriously kept out of sight by the solidist philosophers who came upon the stage almost before the curtain had fallen upon the illustrious interpreter of nature here passingly alluded to. “The humoral pathology,” says Bichat, “is founded on truth, and in a great many cases we must allow that all should be referred to morbid humours.” Andral (Path. Anat.—“Lesions of the Blood”) observes, “I have now stated the facts and arguments which, in the present state of the science, ought to lead us to acknowledge the existence of certain alterations in the blood. What I have already said on the subject, in my opinion sufficiently demonstrates not only that they are often primary, that they precede those of the solids, and that, consequently, the origin of many diseases lies in the blood. If it is true that the mass of the blood may in certain cases be primarily altered, it follows that the existence of general disease is not merely imaginary. In fact, when all the tissues thus receive a vitiated blood, is it not consistent with sound physiology to admit that their regular modes of vitality, nutrition, and secretion, must be more or less deeply modified? We must either admit this conclusion, or deny the influence which, according to every physiologist, the blood exerts over each solid.” That the life of the flesh is in the *blood* is a lesson forced upon us as well by physiology and pathology as it is by reason. We have never heard, I was going to say, of such caprices of nature as beings without hearts—acardiac monsters; but it would be more correct to say, of beings without some fitting provision for the propulsion of the blood. But we know that the absence of a brain, the great centre of nervous life, is not incompatible with the continuance of existence; and that the removal of the head in some of the inferior animals is not attended by immediate arrest of the action of the heart; whilst we daily witness the annihilation

* Some papers, preliminary to this subject, have already appeared in the *Lancet* for 1849.

† I have already devoted one article in the *Lancet* (vide the No. for Dec. 22, p. 655) to the opening of this subject, wherein the literary history of the disease may be referred to.

‡ “When the blood once becomes solid, it displays indubitable symptoms of *vitality*;—vessels are produced, and secretions formed in it; and different alterations of nutrition, resembling those observed in the tissues, may also occur. If we examine whence this coagulated blood derives its vitality, we find that it cannot partake of the common life of the rest of the body, since it very often merely touches the surrounding tissues, without being in any manner continuous with them.”—A Treatise on Pathological Anatomy, by G. Andral, vol. i. pp. 647-8.

of the functions of the spinal cord by disease, without the necessary death of the individual. But the moment we withdraw the influence of the *blood* from an animal, as immediately is the disruption productive, as a direct sequitur, of its death; whilst, if instead of withdrawing it altogether, we do so only partially, a series of phenomena ensues which eloquently bespeaks the difficulty with which the functions of life are carried on upon the diminished supply, and which denotes the struggle to which they have been brought in the effort to support themselves upon the same. If, again, in place of experimenting upon the quantity, we act upon the *quality* of the blood, we arrive at equally serious results in the end, though not without some difference in the aspect and order of the phenomena. M. Gendrin (*Histoire des Inflammations*, tome ii), injected some variolous blood into the circulation of an animal, which was rapidly followed by fatal symptoms; and in his work on fevers, he recounts the particulars of another experiment upon a cat, into the cellular tissue of whose groin he injected some of the blood taken recently from a patient who laboured under a "putrid fever." The animal immediately fell under an aggravated form of typhoid symptoms, and died in about seven hours after. The post-mortem appearances were such as principally depended on rapidly ensuing decomposition; but what concerns our present subject to notice more particularly, is that "the blood throughout the whole body was black and fluid;" in a word, decomposed and dissolved. In the experiment of injecting poisons into the bloodvessels of animals, we are introduced to an illustration of the *more immediately fatal* consequences attendant on a vitiation of the properties of the blood; whilst in diseases where the blood has undergone a palpable and acknowledged deterioration or process of poisoning, as in chlorosis* and yellow fever,† we witness a slower and less

striking influence upon life, because its manifestations are *not at once* suspended by the operation of the latter.

How forcibly do not these facts confirm the great truth of the Mosaeic writer, to which I again invite the reader's earnest attention. I might advert, too, I think, to the relatively *larger proportion* of the fluids of the body as compared with that of the solids, as another proof of the importance of the humors in the economy, an argument in itself in favour of the blood's pretensions to *originate* disease, as I believe it to be the *primum mobile* of health. "Blumenbach possessed the entire *perfectly dry* mummy of a guanche, or aboriginal inhabitant of Teneriffe, presented to him by Sir Joseph Banks, which, with all its muscles and viscera, weighed only seven pounds and a half."* The

expedient to bleed, the blood wore the same general appearance. After a separation had taken place, the serum assumed a yellow shade, often a deep orange, and a portion of the red globules was invariably precipitated. It occurred to me, that if the remote cause resided in the common atmosphere, the blood of all who had inhaled it a certain time would exhibit similar phenomena. It accorded with the pathology I had conceived, to conclude that all who lived in an atmosphere so impregnated were constantly predisposed, and that an additional or exciting cause only would be required to develop the symptoms in form. To ascertain the appearances of the blood, in subjects apparently in good health, I drew it from five persons who had lived, during the whole season, in the most infected parts of the city, who were, to every external appearance and inward feeling, in perfect health. The appearances of the blood could not be distinguished from that of those who laboured under the most inveterate grades of the disease. As this experiment might have been considered inconclusive, unless the blood could be compared with that of those who lived in a purer atmosphere, remote from the evolution of miasmata, I selected an equal number of persons who dwelt on the hills in Baltimore Country, and drew from each of them ten ounces of blood. The contrast in the appearances was so manifest, that no cause for hesitation remained. There was neither a preternaturally yellow serum, nor a red precipitate: the appearances were such as we find in the blood of healthy subjects. A young gentleman having returned from the western part of Pennsylvania, on the 10th September, in good health, I drew a few ounces of blood from a vein on that day: it discovered no deviation from that of other healthy persons. He remained in my family till the 26th of the month, and on that day I repeated the blood-letting. The serum had assumed a *deep yellow hue*, and *copious precipitate of red globules* had fallen to the bottom of the receiving vessel. Of the six persons whose blood assumed the indications of the remote cause, four were seized with fever during the epidemic: the other two escaped any formal attack, but complained occasionally of headache, nausea, and other indications of disease."—*Observations on the Healthy and Diseased Properties of the Blood*, by William Stevens, M.D., pp. 223-5.

* *The Physiological Anatomy and Physiology of Man*, by R. B. Todd, M.D., and William Bowman. Part i. p. 84.

* Although chlorosis may not be thought fairly to come within the category of the *blood poisons* in the same sense as fevers and the exanthemata, yet its eminently humoral essence exposes it to the opprobrium of relationship (though a distant one) with that family.

† Dr. Potter observes, in his *Memoir on the Yellow Fever*, that "in September, 1800, a fever was daily obtruded on the observant practitioner, which, although it had long been familiar to me, had not then been fully estimated. It was remarkable that, in all cases in which it was detected,

primary importance of the humors in the great scheme of animal life is happily instanced in the following quaint sketch:—"Certainly, an adult man, who weighs two hundred pounds, in his first original lay concealed in a very little drop of a seminal liquid, and from so small a beginning growing up to so large a weight, owed all his increase in the solid parts to the supplies he received from the fluids, as appears from the observations of Malpighius, attempted of old by Hippocrates (*De Naturâ Pueri*), upon the incubation of eggs; in which we see the young chicken grows in one and twenty days, from too small a bulk to be seen by the naked eye, to have very firm parts out of the liquid of the white attenuated by incubation."

"Inasmuch," says Andral, "as the blood nourishes the solids, and as without its presence they cannot support life, the state of the solids cannot but be influenced by the state of the blood. The chemist might as well say that the nature of a body does not depend on the nature of the elements that compose it. On the other hand, the solids, considered with respect to their relations to the blood, form but two classes; the one, contributing to *make* the blood, such as those concerned in the actions of absorption, digestion, arterial circulation, and respiration; the other, contributing to *unmake* it, those, namely, concerned in the actions of various circulation, secretion, and nutrition. No one solid, therefore, can undergo the slightest modification, without producing some derangement in the nature or quantity of the materials destined to form the blood, or to be separated from it. Physiology, then, leads us to the conclusion that every alteration of the solids must be succeeded by an alteration of the blood, just as every modification of the blood must be succeeded by a modification of the solids. Viewed in this light," continues he, "there is no longer any meaning in the disputes between the solidists and the humorists; the system appears to constitute but one great whole, indivisible in the state of health, as well as in that of disease; the division of the parts of the body into solids and fluids seems to be a distinction of small importance, and one

that is not always just, since it ceases to exist in the intimate structure of the organs, in which all the grand vital phenomena take place, and in which, also, occur all the changes that constitute the morbid state."* I do not recognize either the force or the correctness of the argument as set forth in the concluding words of the last paragraph. Does Andral mean that because "all the grand vital phenomena take place in the intimate structure of the organs," those phenomena are therefore independent of a healthy quality of blood—nay, that they are not, therefore, more directly dependent upon such? "Physiology leads us to the conclusion that every *alteration of the solids must be succeeded by an alteration of the blood.*" But I am at issue with M. Andral upon the very *premises* of his argument. I deny the logic of his reasoning: I deny that the alteration of the solids ever *precedes* the alteration of the blood; although, when so altered, they may and do react upon the latter by interrupting the physical and vital processes which are exerted upon it by the bloodvessels. What! exclaims the solidist, shall not the earthy and atheromatous deposit in the bloodvessels occasion an alteration in the "manner or the matter" of the blood? And shall not the tubercular or malignant disorganization of the respiratory organs interrupt the vital and physical changes essential to the integrity of the blood? Assuredly they shall, *in their turn*. But whence originated the earthy and atheromatous, the tubercular and malignant alterations, but in *that blood* which now is *secondarily* influenced by those deposits?

Huxham observes, that "a due consideration of the state of the solids is a matter of high importance to physicians; not only in chronic, but also in acute diseases; for they are generally the *primary efficient causes of the particular states of the fluids.*" This authority seeks to illustrate the above principle by describing two opposite states of the blood,—one, in which "the humors are too dense and viscous; in which the blood globules are in too great quantity, and too closely compacted or condensed; in which the serous globules are so likewise;" the other, characterized by "too few blood globules, and those too loosely

* The Commentaries upon the Aphorisms of Dr. Herman Boerhave. By Gerard Van-Swieten, M.D. Vol I. pp. 39-40.

* Andral's Pathological Anatomy—Lesions of the Blood, vol. I. pp. 648-3.

compacted; and in which the serum is too watery and rapid, and sometimes of a ropy, slimy nature," &c. Now, although Huxham does admit these opposite conditions to have a primary and independent origin of their own, he nevertheless sets down their respective operation upon the several organs of the body to the account altogether of the physical, and not of the vital, effects which they produce upon the bloodvessels. Thus, for example, "a strong, rich blood always attends a strong elastic set of vessels, and a weak, watery blood, a relaxed habit of body,"—as though the constitution of the blood took its standard of perfection, or the opposite, from the character of the bloodvessels, instead of itself determining the quality of the latter. But Huxham only followed here in the footsteps of his illustrious predecessor, Boerhaave, in whose "weak lax fibre," and "stiff elastic fibre," he formed the model of his own system of physiology.

We meet with a remarkably diverting example of the truth with which I have opened my present paper—to wit, the exclusion of the blood from a due share in the causation of disease,—in the celebrated doctrine of *Girtanner*, who endeavoured to prove that the principle of life was dependent on irritability, or rather, that irritability is itself the principle of life! "The irritable pulse," says Girtanner, "from the first moment of its existence to that of its dissolution, being constantly surrounded by the body which acts upon it, and stimulates it, and upon which it reacts by its contraction, it follows, that during the period of its existence, the irritable fibre is in continual action; that its existence consists in action; and, that it is not a passive state as some authors have asserted. Hence, external objects having no immediate action upon the nerves, and only acting upon them and producing their different sensations through the medium of the irritable fibre, it is plain that the ideas we have of external objects are not conformable to those objects, but that they are varied and modified by the irritable fibre through which they are transmitted to us. Objects, therefore, appear different according to the different states of the fibres. When the irritable fibre has lost its tone, and fails, either from an access of the irritable principle, or from a deficiency of this principle, it is dis-

eased, and the system of which it forms a part suffers and becomes diseased, through sympathy. All the diseases of animals may be ranged under two heads; to wit, first, the *diseases of accumulation*, caused by the accumulation of the irritable principle and the diminished action of the habitual stimuli; secondly, the *diseases of exhaustion*, caused by a defect of the irritable principle proceeding from the increased action of the habitual stimuli, or from the addition of new stimuli. Under these two classes may be ranged all diseases whatsoever (!)"

But, at the risk even of fatiguing the patience of the *matter-of-fact* reader, I must be suffered to complete this diverting picture.

As though Girtanner had been seized, at the close of the foregoing passage, with some forebodings of the fate of his bantling, he exclaims:—

"Paradoxical as this proposition must necessarily appear to those who have not reflected on the subject, it is nevertheless true, and I shall give the most convincing proofs of it in a *work I am about to publish* (!)"

Girtanner continues—"The effect produced upon the irritable fibre by any stimulus or s , being always equal to $a \cdot b$ " (a representing the force of the stimulus, and b the degree of irritability of the fibre), "it follows, that the value of s and b being known, the value of a is also known. But, admitting an unity fixed and constant, it will be easy, in all cases, to express by numbers, the degree of irritability of the fibre, and the degree of the force of the stimulus, or the value of a and b ; consequently, it will be easy to find the value of s . All the art of medicine, then, consists in finding the value of s , that is to say, in finding a stimulus adequate to restore the tone of the fibre. Thus, if these principles be true, physis, which at present is an art of mere conjecture, will be reduced in time to the certainty of calculation; and, after tables shall be formed to express the value of a and b , and the signs by which they may be known, this calculation will be so simple and easy, that it will form a part of the education of every individual (!) But further, the irritable fibre being the same in all organized nature, diseases and their remedies will, of course, be the same for all organized beings; there will then be no distinction between me-

dicine, farriery, and agriculture, but all these sciences will be confounded and become one, under the general name of universal physiology (!)"

Girtanner then brings these striking principles to elucidate the subject of fever. "When any local stimulus continues to act upon any part of the system, the circulation becomes more rapid, and a fever is the consequence. Is the stimulus weak, a slow fever ensues, which will, by little and little, exhaust the irritability of the system, and the patient will die of a consumption. Is the stimulus stronger, or the fibre upon which it acts more irritable, we shall have an ardent fever, which will exhaust the irritability in a less time. In fine, is the stimulus very violent, or the fibre diseased by an excess of irritability, we shall have a putrid fever, which will destroy the patient, whether animal or vegetable, and will exhaust the irritability in a very short time (!)"*

Well would it have been for suffering humanity had we stuck to the *simple principles* of Girtanner, and, reducing our corporeal infirmities under the discipline of a few mathematical tables, have elevated medicine to the "certainty of calculation!" But, then, we have since embarrassed ourselves with the pretensions of that very inconvenient claimant, the *blood*; and hence the obscurities and perplexities which in consequence we have brought about our ears!

But I crave the reader's forgiveness for so long a digression from the proper subject of this paper—*Erysipelas. A nos montons, donc.*

In introducing this subject originally to the notice of my professional brethren,† I set out with the remark that "I am much mistaken if I do not succeed in establishing the claims of this disease to take its stand in the foremost rank of that category of inflammations which possesses the distinctive characteristics of an origin in a morbid poison, and an immediate connection with an adynamic condition of the system."

I now proceed to redeem this undertaking, as far as the present amount of our knowledge on the subject shall enable me; and, in doing so, I propose to examine these two questions in the

order in which I have enumerated them, and to examine them separately and apart from each other. And, first, of the former.

That there is something very peculiar, if not specific, in this particular form of inflammation, is a conclusion arrived at by the concurrent testimony of all ages, and by the champions of almost every sect into which the sciences of medicine has been cut up. "To rest satisfied that erysipelas is an inflammatory affection of the skin would be to remain in ignorance of its practical nature; for such has been the advance in our method of looking on things, that we have learned to regard the word inflammation* as expressing a very variable state, oftentimes such as by no means warrants depletion nor so-called antiphlogistics. That erysipelas is of the nature of inflammation we cannot doubt: we can imitate its results by applying a blister to the skin; and, when the integument is loose, we get a large amount of cedematous effusion, and often the production of pus in the parts beneath, as in the eyelids." "That erysipelas is an inflammatory disorder few will be disposed to deny; but I think as few will hence infer that we must treat it by depletion, antimony, &c. Inflammation is a condition which occurs in states of the system most

* "When the augmentation of the natural excitability is attended by pain, redness, and swelling, it is termed inflammation. This metaphorical expression, invented in the infancy of the science, was originally intended to represent a morbid state in which the parts affected appeared as if they had been actually submitted to the action of fire. As it was originally adopted into medical language without having any precise or well-defined idea attached to its signification, either as regards its intimate nature, the symptoms that indicate its existence, or the morbid lesions that characterise its progress, it has now become so vague in its signification, and in its interpretation so arbitrary, that it has really lost all value as a term of science; and, like an old coin from which the original impression has been effaced, should be forthwith withdrawn from circulation, as calculated to produce constant error and confusion. In fact, inflammation can now only be considered as the expression of a complex phenomenon, comprehending under it several other phenomena which have neither a necessary nor even a constant dependence on each other."—*André's Pathological Anatomy, Preliminary Observations*, vol. i., pp. 12-13.

Another distinguished physiologist of the present day has said—"Nothing is better known in the aggregate than the indications and tendencies of that state which pathologists have long been accustomed to denominate 'inflammation'; and, in their detail, few things are less clearly understood and satisfactorily explained."—*The Physiology of Inflammation and the Healing Process*, by Benjamin Travers, F.R.S., p. 24.

* Vide Girtanner's *Memoir on the Laws of Irritability*, translated by Dr. Beddoes.

† *Lancet*, December 2nd, 1846, p. 635.

widely different, as between simple pustular acne and violent typhoid small-pox. Pustules result in both, and both are inflammations of the skin; but, to say no more than this would leave us far off from anything like appropriate treatment, which, indeed, can never be determined by classifying a disease, but by studying the state of the system in which it occurs.*

But, now to address ourselves to the difficult question, upon what circumstance, or combination of circumstances, we are to account for the peculiar features which the erysipelatous inflammation (when and wheresoever occurring) is in general observed to put on? If erysipelas be in reality an *ordinary* inflammation, then let the supporters of such opinion explain the causes of its frequently sudden appearance and as sudden disappearance—of its erratic habits—of its occasional dependence upon a wound, but more frequent occurrence without assignable cause—of its disobedience in general to depletory treatment, and marked subservience to the administration of stimulants—of its inability to limit its range by the effusion of coagulable lymph, as in the instance of ordinary or common inflammation, &c. &c. &c.?

That these peculiarities cannot be explained upon a reference to the nature of the structure involved, is plain from the very different behaviour of "*common inflammation*" when developing itself in the same texture—viz., in the cutis,—an opinion, however, I must admit, directly at variance with that of Mr. Lawrence, who lays it down that there is no difference between erysipelas and other inflammations, and that any anomalies which may seem to exist in the former are referable to the peculiarities of the cutaneous and cellular structures in which it occurs

But that this position of Mr. Lawrence's is untenable must be evident from the circumstance to which I have just alluded,—namely, that the skin is subject to "*common*" inflammation (as Mr. Samuel Cooper expressively designates it); and which common inflam-

mation, when attacking that structure, observes a line of conduct in every respect the reverse to that of the erysipelatous. I ought, however, to remark that Mr. Travers has lent the weight of his name to that view of the question which seeks to account, in some measure, for the peculiarities of erysipelas upon the argument of peculiarity of structure involved:—"My own opinion is, from careful reflection on its history and phenomena, that erysipelas derives its local peculiarities from those of its seat,—namely, the membranous capillary circulation; and from the intermediate influence of the nervous system between this and the heart, and all the other organs of the body, its peculiar 'pathology.'"

"It has been supposed," observes Hunter, "that the different species or varieties of inflammation arise from the difference in the nature of the part inflamed; but this is not the case; for, if it was, we should soon be made acquainted with all the different inflammations in the same person, at the same time, and even in the same wound: for instance, in an amputation of a leg, where we cut through skin, cellular membrane, muscle, tendon, periosteum, bone, and marrow, the skin should give us the inflammation of its kind, the cellular membrane of its kind, the muscle of theirs, the tendons of theirs, the periosteum, bone, marrow, &c. of theirs; but we find it is the same inflammation in them all: it is the adhesive in them all if the parts are brought together; it is the suppurative if the parts are exposed."—Vol. iii. "*Fundamental Principles of Inflammation*," p. 313.

That the specific and *unhealthy* characters of the erysipelatous inflammation are not to be explained upon the assumption of its predilection for strumous subjects, or for those otherwise debilitated and depraved in constitution, is demonstrable from the fact that we see it daily set up, as well in the young, robust, and temperate, as in those more advanced in life, the cachectic, and the debauched. It is as common in the infant as in the sexagenarian—in the artisan as in the noble—in the one sex as in the other.*

* Dr. Gull on the "*Alliances of Erysipelas*," vide a paper read at the South London Medical Society, *MEDICAL GAZETTE*, vol. xlii. p. 999.

† "The skin, like all other parts, is often the seat of *common inflammation*."—*Cooper's Surgical Dictionary*, article *Erysipelas*, p. 481, ed. 6th.

* I have had no personal experience of the greater frequency of erysipelas among women than in our own sex, although, that such is the case is usually laid down by systematic writers on the disease, Copland amongst others.

Upon what, then, do its peculiarities depend? "It does not appear to me," observes our lamented lexicographer, "that any very exact information has been established respecting the causes of erysipelas. We absolutely know nothing about the immediate cause; the prevailing ideas concerning the predisposing causes are vague; and only those causes termed *exciting* appear entitled to much confidence"—(Cooper's Surg. Dict. p. 453). Upon what, I repeat, do its peculiarities depend; if not upon the nature of the structures involved—neither upon the existence of any of the cachexias in those on whom it fastens—nor in sex, age, or habit of body? If upon none of these we may throw ourselves for a solution of the question, from what quarter are we to expect a glimpse of light that shall open a path to a better understanding of its nature, and, as a direct consequence, to some fixed and rational principles for its treatment?*

If we turn to the *solidists* in our difficulties, we derive but little satisfaction at their hands. In their "weak, lax," or "stiff elastic fibre," we shall find but little to help us out of these perplexities.

[To be continued.]

* Although it may be difficult to carry the "*ablatâ causâ*" principle into immediate operation in this class of diseases, yet in none can it be more important to address ourselves to the *origo mali*, if the view which I take of the "immediate" cause of erysipelas be the correct one. I cannot but think that Dr. Graves has made a false move in medical philosophy, when, in the present inquiring age, he inculcates such principles as these:—"The moment we attempt to inquire into the causes and modes of vital action we begin to, retrograde, and all becomes hypothesis and confusion." And, in recommending a closer study of "morbid anatomy" as the most unerring guide to the proper comprehension of disease, and to its best directed treatment, he observes—"In order justly to estimate its importance (morbid anatomy), we should recollect that the first alteration in the texture of a part is not the cause but the consequence of disease; for in every healthy organ the texture is natural; and as every change of texture is produced in consequence of derangement in the vital action of the vascular system of the part, it is obvious that structural alteration must in the first instance be always produced by functional derangement. Thus the physical alterations which attend external inflammation—the tumefaction, the heat, the redness, are not the causes but the consequences of disease. But in thus reducing them to the rank of symptoms, do we diminish their importance? Certainly not; for, being immediately connected as effects with the primary cause, they prove the most useful of all symptoms in enabling us to ascertain the seat and progress of diseased action. In this respect they possess a manifest advantage over the general or constitutional symptoms. Thus, in cases of spontaneous gangrene, phlegmonous inflammation,

ON THE
TREATMENT OF THE "WARTY"
ULCERS OF MARJOLIN, BY
MEANS OF THE CHLORIDE OF ZINC.

By H. FEARNSIDE, M.B. LOND.,
Physician to the Preston Dispensary.

In the May number of the Dublin Quarterly Journal of Medical Science, at the close of a "valuable paper on the 'Warty Ulcer of Marjolin,' by Dr. Robert Smith, there occurs the following passage:—"Were I to attempt the cure of this disease by caustic, I would feel inclined to place most reliance upon the chloride of zinc, the efficacy of which in destroying cutaneous cancer has been highly extolled by Dr. Canquoin, of Paris, and likewise by Dr. Uré."

Having successfully employed this agent in an example of the disease which fell under my care about two years ago, it has appeared to me that a short history of the case may probably be deemed of sufficient interest to merit publication.

G. H., æt. 55, a large unwieldy man, of phlegmatic temperament, came under treatment in April 1848. His occupation was that of a porter. He stated that his habits were temperate, but he had the aspect of a man accustomed to indulge in malt liquor. He had always enjoyed good health. His parents died at an advanced period of life.

About nine years previously, in unloading a dray, he sustained a severe injury to the front of his right leg by its coming into violent contact with a large and heavy cask. A considerable amount

tion, or erysipelas, what practitioner would be contented to draw his indications from the general symptoms, disregarding the appearance of the affected part?" (Graves's Clinical Medicine, p. 15, ed. 1st.) I will answer this question by propounding another to the writer. In the treatment of the cases of glanders and button-farcy so graphically detailed in the forty-fourth chapter of this same work, was a knowledge of the "immediate" cause of the inflammatory swellings over the exterior of the body of *insignificant* import in comparison with a study of those local appearances themselves? Of what advantage were the usual appliances for inflammatory swellings under such circumstances? And, under an ignorance of the "*immediate cause*" of those inflammatory swellings, how greatly would not the fatal issue have been precipitated by an active system of depletion for their relief!

of inflammation ensued, upon the subsidence of which there remained a circumscribed swelling of the size of a pullet's egg, which underwent little or no change for some years. About ten or twelve months prior to his coming under my notice, he began to experience pain in the tumor, which slowly increased in size, and acquired a dark red colour: the skin covering it was indurated and uneven. Poultrices were applied for some time, until the skin gave way, and an open sore resulted, which presented a grey unhealthy appearance. The discharge from it was thin, fetid, and often bloody. From the surface of the ulcer arose a diseased growth, which soon acquired considerable elevation, and from which profuse hæmorrhage took place from time to time: on being removed by any cause it was rapidly reproduced. When I first saw him, the morbid growth presented the following characters:—From the centre of the front of the right leg, occupying a space of about three inches in diameter, there sprung a dark grey substance, which projected at least two-thirds of an inch above the surrounding skin. Its surface had a granular appearance—at first view not unlike the head of a cauliflower: on closer examination, it was seen that this was occasioned by the prominent extremities of coarse fibres which arose from the base of the ulcer, and were collected into masses, separated from each other by deep fissures. The margin of the sore was thickened, elevated, and possessed little or no connection with the fibrous structure above described: the surrounding integument had undergone considerable warty induration and discolouration. A thin, ichorous discharge proceeded from the part; the pain experienced was not violent; there was no enlargement of the popliteal or inguinal glands. He complained of being weakened by repeated loss of blood, but his health was otherwise good. He had been previously under the care of one or two medical men, and had been advised to submit to amputation of the leg, on the supposition that the disease was fungus hæmatodes.

He was seen with me by my friend Mr. Noble, who considered the case a favourable one for the employment of the chloride of zinc; and, accordingly, it was determined to attempt the cure of the disease on the plan recommended

by Mr. Alexander Ure (MED. GAZ., vol. xvii. p. 891).

On its first application, the remedy was mixed with flour (Canquoin's formula). But little pain was occasioned by it, and the resulting slough was not deep. When it was next employed, it was blended with pure sulphate of lime, as proposed by Mr. Ure. The whole of the morbid growth was covered to the depth of a third of an inch with a paste composed of one part of chloride of zinc and two parts of sulphate of lime. The application gave rise to severe pain, which was only partially under the control of opium. At the expiration of four days an extensive and deep slough was produced, which separated in the course of the ensuing week or ten days. The greater part of the sore was then covered with healthy-looking granulations; but, to get rid of two or three small masses of whitish semi-cartilaginous substance, as well as to overcome the indurated condition of the margin of the ulcer, it was requisite again to have recourse to the caustic paste. The subsequent progress of the case was, upon the whole, highly satisfactory. No hæmorrhage ensued after the first complete application of the chloride of zinc. In the course of a month small florid granulations had risen to the level of the adjoining surface, and cicatrization commenced. The complete healing of the sore was delayed for some time by the patient's imprudence; for, considering himself well, he could not be induced to submit longer to regular treatment. After the lapse of three months, however, a small ulcer of the size of a shilling was all that remained of the apparently formidable disease; and he afterwards reported himself as cured.

REMARKS.—The case of which an outline has been given above exemplified well the characters of a peculiar form of ulceration sometimes seen in old cicatrices, and to which the attention of the profession has been specially called by Marjolin,* Mr. Cæsar Hawkins,† and Dr. Robert Smith,‡ to whose several papers I beg to refer for a complete history of the affection. An ac-

* Dictionnaire de Médecine.

† Medico Chirurgical Transactions, vol. xix.; and MEDICAL GAZETTE, vol. ii. 1840-41.

‡ Dublin Quarterly Journal of Medical Science, May 1850.

quaintance with its distinguishing features is important, both from the severity of the disease in itself, and also from its resemblance to fungus hæmatodes, with which it has several times been confounded.

As before stated, the case is recorded for the purpose of illustrating (so far as one case can) its successful treatment by cauterisation with the chloride of zinc. Where the diseased growth is of moderate size, as in the case detailed above, and where it has not involved (at least seriously) the subjacent periosteum and bone, this mode of attacking it seems to be principally applicable.

Respecting the nature of this disease some diversity of opinion has prevailed.

In his first memoir upon this subject, Mr. Hawkins remarked that "it did not produce any contaminating influence upon the absorbent glands, and had no tendency whatever to reappear in a distant and unconnected part of the body;" but, in a lecture published in 1841, he viewed its cancerous nature as more decided. Dr. Robert Smith declares it to be "undoubtedly a form of cutaneous cancer;" but he thinks that it is "malignant only in the lowest degree."

The microscopical evidence as to its cancerous nature is negative. Rayer considers the peculiar fibrous growth as the result of hypertrophy of the papillæ of the skin. This explanation is also offered by Mr. Paget (*MEDICAL GAZETTE*, vol. i., p. 286, 1838-9), who states that he "finds this disease of the papillæ connected with a peculiar and intractable form of ulceration, which occurs not unfrequently upon the shins. It is remarkable for the manner in which it spreads down to the periosteum of the tibia, and even into the bone itself, from whose medullary tissue a soft, fungous, and irritable mass of vascular granulations arises, and occupies the centre of the sore."

It would thus appear that this diseased structure belongs to the class of morbid tissues described by Professor Bennett under the name of "*epithelial canceroid growths*." To this head must be referred many cases of so-called cancer of the lip, chimney-sweepers' cancer, cauliflower excrescence of the uterus, and some other forms of disease which, although possessing characters of considerable gravity, yet differ mate-

rially in structure from true cancerous or malignant growths.

But, from its occasionally affecting the absorbent glands, and its removal being followed by unequivocal cancerous disease elsewhere (as in Dr. Smith's cases, I. and IV.) we must admit that in some instances it has a more decidedly malignant nature; thus affording an exemplification of a class of cases lying on the confines of benign and malignant disease, but capable of assuming the character of the latter under favourable circumstances.

INCOMPETENCY OF MEDICAL EVIDENCE IN CERTAIN CASES.

In a late trial before the Supreme Court at Lowell, in a case of alleged lunacy, medical testimony was brought to bear upon both sides. The petitioner, an aged man, among other testimony offered by him to prove his sanity, brought forward several most respectable and distinguished physicians of this city; the respondent, who was the guardian, having Drs. Bell and Fox, of the McLean Lunatic Asylum, on his side. Judge Metcalf, in his charge to the jury, ruled all the medical testimony as *incompetent*, excepting Drs. Bell and Fox's, they being considered the only *experts*. However, the intelligent jury thought differently, and rendered their verdict for the petitioner,—a just rebuke to such a judicial decision. Who are considered competent to certify to insanity in case of admission into lunatic asylums? Would not these same medical gentlemen have been deemed suitable? If so, we really should like to know if they are not *experts* enough to tell when their patient has recovered his reason? Such partiality for *experts*, in judicial investigations, is getting to be more fashionable than wise. Common sense is, after all, the best guide for a magistrate; for then he can ascertain for *himself* who is qualified to give an opinion, and who is not. This is also the best guide for a professional, as well as a non-professional man, in ascertaining whether there is soundness of mind; and we are surprised to learn that a magistrate should feel inclined to exclude medical testimony in such a case, from the fact that the witnesses were not considered *experts*.—*Boston Medical Journal*.

. The question is, Are they competent to certify or give testimony, unless they have had experience in cases of insanity?

PRESENTATION OF THE BACK AT THE FULL PERIOD OF GESTATION.

BY W. B. KESTYEN, M.R.C.S.

PRESENTATIONS of the back or loins are forms of preternatural labour so rarely met with, that the following case seems worth recording:—

Mrs. D—, aged about 30, at the expiration of the full period of her fifth pregnancy, was taken in labour at 5 a.m. on May 26th, 1869. I saw her between 6 and 7 o'clock; the os uteri was fully dilated, the pains strong, and occurring regularly. The membranes were entire. I could not then reach the presentation sufficiently to form an exact opinion of its nature. The pains continued regular and strong. At 11 a.m. I could detect a broad flat surface about the brim, which clearly was neither head nor breech. The mother was becoming much fatigued, and no further progress made in the descent of the child, still above the brim of the pelvis. The membranes gave way at 1 p.m. I could then bring my finger in contact with a greater surface of the presentation: I felt what I supposed to be a shoulder, and considered that the occiput was resting on the pubis. I then considered it to be my duty to turn, without waiting for assistance, as the pains had been strong for between seven and eight hours, and the patient's strength was becoming exhausted, and there appeared no chance of the position of the child being changed by the natural action of the uterus. On passing my hand into the uterus, I found that what I had supposed to be the shoulders was the crest of the ileum; and that my hand, in passing to the fundus of the uterus, traversed the length of the back, and came in contact with the vertex, situated posteriorly and superiorly in the fundus of the uterus. I then passed my hand (the right hand) over the body of the fœtus anteriorly, and, fixing my forefinger in the groin, brought down one leg into the vagina; at the same time pressing the body of the child upwards into the cavity of the uterus, and delivered footling, bringing down one extremity only.

The child was apparently still-born, but the means employed for its resuscitation were successful after having been perseveringly employed for an hour.

The mother had a speedy and perfect recovery. It may be remarked, that in her preceding labour I had been obliged to have recourse to the use of the forceps for the delivery of this patient, owing to an arm having passed into the vagina with the head.

REMARKS.—The rarity of this form of preternatural labour is shown by the following notices, collected from numerous obstetric authors:—

Dr. Merriman, in his treatise on "Difficult Parturition," states:—"In the very extensive practice of my uncle, the late Dr. Merriman, and in my own practice, amounting together to nearly 20,000 labours, no instance has occurred of either of these presentations, except in one or two cases where the mother had not completed her seventh month of utero-gestation, and in these the children passed double through the pelvis." Dr. Merriman, however, relates one case which was communicated to him by a practitioner in the country, and states that he was informed by another friend that he had twice met with the presentation of the back.

The advice given by Dr. Merriman, on theoretical grounds, for the management of this case, is precisely such as it was found practically necessary to follow in the case that has been now related. "Should such an unusual case occur," observes that author, "it is possible that in the course of the labour the presentation would be changed to one more favourable. If no alteration in the position took place spontaneously, the introduction of the hand would be necessary, as soon as the parts were sufficiently dilated, to bring down the feet, and to deliver before the strength of the patient was exhausted." p. 96.

Dr. Collins, in his "Practical Treatise on Midwifery," does not mention this presentation. It is surprising that, in such a vast mass of personal experience as therein recorded, a similar case should not have occurred.

Neither, in Dr. Robert Lee's "Lectures on the Theory and Practice of Midwifery," nor in the same author's "Clinical Midwifery," which contains the histories of 546 cases of difficult, preternatural, and complicated labour, do I find any case of presentation of

the back or loins recorded; and Dr. Lee has informed me that he has never met with an undoubted case of back presentation in his large experience.

Dr. Churchill places this presentation in his second division, but does not speak of having met with a case of the kind. Dr. Ramsbotham says it may occur, but is very uncommon. Dr. Blundell mentions only its possibility. Dr. Burns regards it merely as a stage of breech presentation that would terminate in that manner if left to nature. The narrative of the above case proves that such is not necessarily the course of this position. Although averse to meddling midwifery, and having almost unlimited faith in the powers of nature, yet I conceive that I should not have done my duty to my patient, had I left her to wait until nature changed the position of her child.

I am indebted to my friend, Dr. Allan, of Islington, for the opportunity, in his extensive library of obstetric works, of examining numerous French authors, and have found mention of back presentations in several. Thus Madame de Boivin* describes four positions of dorsal presentations:—1. The head placed anteriorly above the pubes, the back posteriorly; the left side of the infant corresponding to the right side of the mother: the nates and feet being in the fundus uteri. 2. The head placed posteriorly, the pelvis anteriorly; the right side of the child corresponding to the right side of the mother. 3. The head to the right side. 4. The head to the left side. The directions given by Madame de Boivin for the management of these cases are most minute, but appear more theoretical than experimental. Madame de Boivin mentions its occurrence six times in upwards of twenty thousand cases in her practice and at the *Maternité*.

Baudeloque† also describes four positions of back presentations, and gives very precise instructions for the conduct of the labour, but does not state that he had ever met with the presentation.

Velpeau‡ likewise refines on the management of this form of preternatural labour, and also gives an engraving thereof, but does not state that the case had occurred to him.

Holloway, July 1850.

MEDICAL GAZETTE.

FRIDAY, SEPTEMBER 6, 1850.

SOME months since we called attention to a case of alleged poisoning, which occurred in the County of Surrey, in which the magistrates refused to make any allowance for a chemical investigation, beyond the fee awarded by the Medical Witnesses' Act, and which we need hardly say, is wholly inadequate for researches that may occupy two or three days. The facts as they have been communicated to us are as follows:—A young woman died very suddenly without any previous illness. No poison was found, and poisoning was not even suspected, as she was living on good terms with her relations, and there was no apparent motive for self-destruction. A fee of six guineas was demanded for the chemical analysis—the coroner refused to grant more than two guineas: but he could find no one to undertake it upon these terms. In the end the analysis was made, after a week's delay; and it was then distinctly proved that the deceased had died from arsenic. But for the analysis, the verdict would probably have been "death from natural causes," since some of the chief symptoms of poisoning by arsenic were absent.

This, then, was a case in which a proper chemical investigation was really required. The answer to an application made by the coroner to the magistrates of Surrey for a special fee, is subjoined:—

"DEAR SIR,—I am directed by the magistrates to express to you their regret that they do not possess the power, under any act of Parliament, to make such an order. Under the existing statutes the magistrates have no original power either to order payment, or to determine the amount of fees to Medical Witnesses, but that power is

vested in the coroner both by stat. 6 and 7 W. IV., c. 89, and 1 Vict. c. 68, and the only power which the magistrates possess in this respect, is to order payment out of the county rate of the fees advanced by the coroner according to the scales established by the first of these acts.—I am, dear sir,

"Yours truly,

"WORONZOW GREIG,

"Clerk of the Peace.

"To —, Esq.,
Coroner for Surrey."

June 27, 1850.

The result has been, that the Vicar and principal inhabitants of the village in which the death occurred, have raised the amount by subscription; but we ask—Is it right that the public justices of the country should rest upon so slender a foundation as this? Is it possible that secret murders by poison can be brought to light under such a system as this? It is said that in Surrey, deaths from poisoning are rarely or ever heard of. This can create no surprise, when it is known that the magistrates of the county positively refuse to pay the fair expenses of the investigations required; and thus hold out the strongest encouragement to the concealment of crime. It is unreasonable to suppose that the county coroners should pay these special expenses out of their own fees; and it cannot be expected that such investigations will be made gratuitously by persons competent to undertake them, or that the inhabitants of the Surrey villages will, as a general rule, tax themselves in order to pay charges which really concern the proper administration of public justice.

In the late mysterious death of a female at Clapham, the proceedings were arrested, because the coroner could not, and the magistrates of Surrey and the chief Commissioner of Police would not, issue an order for an investigation and analysis. Owing to this, the mystery of that extraordinary case, in which chloroform was suspected to have caused death, has never been cleared up.

We, however, deny the statements contained in the letter of the magistrate's clerk regarding their want of power to pay special fees to medical witnesses. Such fees are frequently paid by the magistrates of most other counties in England, except Surrey and Middlesex. An act of Parliament is certainly not required for the exercise of this power. The fees are a fair and necessary charge on the county rates, and if allowed by the magistrates at Quarter Sessions, there is no rate-payer that could reasonably demur to the propriety and necessity of such an allowance being made, or compel the Bench of Magistrates to refund the money so paid by them for the benefit of the county, and for the due administration of public justice. The truth is, they have the power to order these expenses, if they choose to exercise it, just as much as the magistrates of other counties, who have not the meanness to raise this technical difficulty.

In the meantime, the decision of the Surrey magistrates should teach all practitioners who undertake these researches, that the maximum fee which they have to expect, whatever time, trouble, and expense they may have devoted to the investigation, will be a payment of two guineas! The evil would speedily be remedied if medical practitioners, unused to such researches, declined to undertake them.

Since writing the above, we find that this false economy regarding the payment of fees to medical practitioners at coroners' inquests has been strongly denounced from the judicial bench, although the censure of the learned judge was directed against the coroner, when the county magistrates were really the parties who had thrown an impediment in the way of public justice.

A man was tried at Wells before Mr Justice Coleridge on a charge of wilful

murder by cutting the throat of a person. An inquest was held, but the coroner would not allow any medical investigation to be made, and the jury came to no satisfactory verdict. On a private examination of the body, it was pretty clear from the nature and situation of the cuts in the throat, as well as the presence of other injuries, that the deceased had been the victim of homicidal violence. The prisoners were acquitted. We quote the following remarks from the report of the trial.

"Mr. Justice COLEBRIDGE said, he did not know the name of the coroner who had held the inquest upon this body, but he was much wanting in his duty in not having called in medical testimony; because, if he had done so, it was impossible his jury could have separated without returning a verdict of wilful murder against some person unknown; and then persons' attention would have been directed to it, and probably a different result might have been arrived at; either the prisoner might not have been put upon his trial at all, or else further evidence might have been adduced against him. Either way, he thought the coroner extremely wrong; and if any coroner went upon a system of abstaining from calling medical evidence for the purpose of saving expence, or for other reasons, he might lay himself open to proceedings in the Court of Queen's Bench, and subject himself to extremely unpleasant consequences."

"In exoneration of the coroner it is stated by the reporter that the magistrates are so particular at the quarter sessions about the expenses of coroners, that these gentlemen are really afraid to call in medical or other aid. It had long been anticipated that in consequence of the difficulties thrown in the way of coroners by the magistrates with regard to the allowance of expenses, the administration of justice would be impeded; and now we have a glaring instance of it."

Having thus an exposition of the law as it applies to coroners, we should be glad to know whether county magistrates who refuse to indemnify coroners for the necessary expenses of inquests,

do not also expose themselves "to unpleasant consequences." At present they appear to set at defiance all rules of reason and justice.

We propose, in the first place, to bring these reports, *seriatim*, under the notice of our readers, pointing out the peculiar features which they may present; and in the second place, by constructing a few tables from the statistics they may contain, to exhibit, so far as they afford materials, the collective information which they may possess.

1. LINCOLN.—The directors of this asylum justly claim the honour of its having been the first institution in Great Britain in which the non-restraint system was efficiently carried into practice. To Mr. Hill, the former resident medical officer of Lincoln Asylum, the directors accord the merit of having introduced, and shown practically, the advantage of, a humane system of control and restraint which should supersede the barbarities of coercion-chains, handcuffs, strait-jackets, &c. &c.

The report of the Lincoln Asylum contains a series of judicious practical observations on the minor contrivances which experience has suggested, to meet

various inconveniences and difficulties which arise in the management of the insane. "The special difficulties of an asylum," this report observes, "are the proper department of the house-surgeon and matron, as the medical economy is that of the physician." The subjects of the "minor contrivances" here referred to, are—escape, violence, insomnolence, noisiness, breakage, refusal of food, perverted instinct, indecency of action and of language, irretention of the bladder and bowels, fits, suicide and sickness. The observations on these several topics abound with such valuable practical hints as must be of service to all entrusted with the management of insane patients, whether in asylums or under private care, as they are the fruits of much practical experience.

2. HANWELL.—"Cheerfully and gratefully THE COMMITTEE terminate their functions by presenting the Report of their Proceedings during the past year. They are cheerful as they commenced—have carried on—and now conclude—the fulfilment of their duties, deeply impressed with their interesting importance, and satisfied by their conviction that they have been usefully discharged."

"THE COMMITTEE, however, perceive that they have *few novel topics whereby to awaken any peculiar interest in the public mind.*" Nevertheless, "the COMMITTEE" flatter themselves that their report will afford information to the medical profession and to other asylums; and "that it will not be unwelcome to *inquiring philanthropists, or to those gentle spirits who have so often manifested an interest in a chority, which has won so much attention, and afforded an example of extensive and generous good.*"*

These gentlemen of "THE COMMITTEE," who honour their collective dignity by capital letters, confess, somewhat reluctantly we think, that they "have indeed experienced, on the part of the medical and superior officers, an intelligent, indefatigable, and kind-hearted assistance which they cannot too highly commend;" yet they throughout speak of their medical staff as quite secondary, and in a tone of patronization unbecoming their relative positions. The directors of the Lincoln Asylum remark that "the special difficulties of an asylum devolve

upon the Resident Surgeons and the Matrons;" but the directors of the Hanwell Asylum seem to be quite ignorant of the fact, that individually the members of their medical staff are capable of the superintendence of an asylum, and that their magisterial functions endow them with no special fitness for such an office. The reverse of this would seem, however, to be the opinion of the twenty-one magistrates of Middlesex, who compose "THE COMMITTEE," if we may judge from their own self-complacent report. This public document is one uninterrupted song of self-praise and self-gratulations. In the estimation of its authors, the entire success of the institution is derived from *their labours*; the completeness of the details of its several parts is attributable solely to *their* superintendence; the restoration of its inmates to health results solely from *their* superior management.

Under such impressions, however false, we are not surprised at the cheerful tone in which they commence their report. At the same time, from anything that we can discover therein, we see no reason to think that "our Asylum" will become "an ornament to the county, and an example to the land!" over and above all others, until, at all events, the reports of "THE COMMITTEE" consist less of *ad captandum* common-places, and extravagant self-laudation. This, however, is a perfection which cannot be attained until these gentlemen have learnt to place a proper value upon the services of their medical staff, and have discovered the true position of their medical officers.

We perceive from public advertisements of the committee of visitors of the new asylum at Colney Hatch, which is to contain 1000 patients, that the same system of medical degradation is to be perpetuated. For so large a number of patients, two resident medical officers are deemed sufficient. And why? Because the appointing magistrates regard themselves as more competent than medical officers to the immediate and constant superintendence of so large and complicated an institution.

Dr. Conolly states in his report, which is permitted to form merely an appendix, that although severe cases of diarrhoea occurred in the asylum, and although

* The italics are our own.

cholera had appeared at Brentford, about two miles distant from Hanwell, yet that owing, under Providence, to the precautions taken, no case of cholera occurred in the asylum.

The usual gratuitous course of clinical lectures was delivered by Dr. Conolly, with the assistance of Dr. Hitchman.

Dr. Conolly reiterates the assertion, that "the substitution of attendants' hands, and the selection of attendants merely on account of their physical strength, has never formed any part of the system of non-restraint as pursued at Hanwell." We have on former occasions expressed our views in relation to the non-restraint system; we shall here take occasion to make a few further remarks upon this subject.

Society undoubtedly owes a large debt of gratitude to those who have followed so perseveringly the example that was set first in France by Esquirol, and afterwards at Lincoln, by Mr. Hill. But, at the same time, society should not in return consent to be imposed upon by a name. The public is told, and believes, that the phrase *non-restraint* signifies the absolutely entire removal of every check upon the voluntary movements of the insane. Common sense, however, will not fail to recognise somewhat powerful means of *restraint* in the walls of asylums, their padded rooms, their seclusion-rooms, their numerous attendants, their padlocked garments, &c. &c. We do not say that these are not required, or are too severely employed; on the contrary, we emphatically assert that they are indispensable, and moreover that they are now used with humane and kind consideration; yet we cannot but regard it as a deceptive use of words, to call the present system of the management of the insane one of *total non-restraint*, instead of simply one of *humane restraint*. An examination of any one, or all of the present Reports will justify these remarks.

We agree with Dr. Conolly that the close of the first decennial period of "this great experiment" would have been a fitting occasion for the managers of this asylum to have given a detailed and explicit public statement of its results. We suppose that the performance of this duty would have involved the performance of another—viz., the confession that to others than themselves,

is due nearly all the credit that may attach thereto. We cannot but mark the striking difference in the expression of two parties here concerned. "THE COMMITTEE" say, we have done this, we have done that, we have done all; but Dr. Conolly, whose wise and judicious superintendence controlled and directed the whole machinery, modestly says—"My inward thought, in all the steps of the attempt which it has been my privilege to make, has still ever been, *Quia fuisti adiutor meus*!"

3. The report of The FRIENDS' RETREAT, near York, may afford interest to its supporters. It is a short, business-like affair. What statistical information it may afford will be found below.

4. The principal and almost the only fact conveyed in the Report of the WEST RIDING OF YORKSHIRE Pauper Lunatic Asylum, is a grave and melancholy fact—the appearance of cholera in the institution, and its spread to a serious extent. The medical officers report it to have been communicated to their inmates from an adjoining workhouse. "The first alarm as to the presence of cholera within the asylum, was excited by the illness of a female brought in on the 17th September, from Gomersale Workhouse, where it was stated two persons had died of cholera on the previous night." From this patient the disease spread to others in the same gallery and room, and to the attendants. Subsequently, other cases occurred simultaneously, in all parts of the institution, the origin of which was not so distinctly traceable to contagion. The whole number of deaths during the month of October was eighty-five! The report states, somewhat pointedly, that one of the days of highest mortality was "the day of the Bishop's visit to the asylum." The total number of patients was six hundred and thirty-three. This report is singularly deficient in statistical information.

5. SOMERSET COUNTY.—This report is drawn up by the superintendent, Dr. Boyd, and presented to the Committee of visitors, who in Somerset seem to be wiser as to knowing their own position, than their fellows in other general features of the report in this asylum.

system now almost universally adopted, that of substituting moral for brute force in the control of the insane.

Dr. Boyd takes the opportunity of this report, to call the attention of pathologists to the dependence of general paralysis on "softening and other results of inflammation of the spinal marrow, and frequently of the ventricles and membranes at the base of the brain." Dr. Boyd states that he has not found this observation in any British writer: we may, however, refer him to our notice of Dr. Winn's treatise on General Paralysis, in which the same opinion is expressed. We quote the following:—"With regard to the pathological appearances, we observe that they present all the varieties and contraries found in the crania of the insane, in apoplexy, and in paralysis, with this one additional feature, that the results of inflammatory action were more frequently found than in simple insanity." (*M&D. GAZ.*, N. S., Vol. viii. p. 861.)

6. GLOUCESTER.—In this asylum, also, the "non-restraint system" is reported to have had full trial. Here, also, a truly charitable plan is about to be carried into effect—viz., provision for the gratuitous admission, in the earliest stage of the disease, of a limited number of those whose position, just above parochial aid, precludes their admission as county patients, but whose means are inadequate to the payments required for maintenance in the subscribers' "part of the establishment." We shall rejoice in the completion of this good intention.

7. ABERDEEN.—It does not appear from the report that the "non-restraint system" is regarded by the officers of the Aberdeen Asylum as the *ae plus ultra* of the management of insane patients. No direct mention of this system is made; but occupation, amusement, and the granting a considerable degree of personal liberty, are among the principal means of cure that have been here adopted.

The report contains carefully drawn up tables, which illustrate various points in the history of insanity. These will be noticed further on.

8. MONTROSE.—We feel called upon to object strongly to one proposition contained in this report—that is, the

employment of chloroform in order to overcome the refusal of food.

Dr. McGavin relates a case in which it was attended with success, and was not followed by any ill effects. This, however, we may suggest, is a better result than can be looked for in every instance. In the case given, "the patient was plied with chloroform, and while partially under its influence he eat (ate) and drank everything put before him, laughing and cracking jokes the whole time." The experiment, we may observe, might have resulted in no laughing matter. We are informed by a dentist in large practice in London, that whenever he has seen any ill consequences follow the use of chloroform, it has been when administered on a full stomach, and this is strictly in accordance with the experience of others. We mention this by way of caution in reference to the use of chloroform for compulsory feeding.

9. PENNSYLVANIA.—This hospital enjoys a considerable celebrity in the United States. We perceive that the treatment here consists principally in the employment of moral influence, combined with so much physical exertion as shall effectually maintain bodily health, while diverting the mind from dwelling upon its own morbid impressions. We find workshops, out-door labour, a museum, a reading-room, lectures on natural sciences, and musical entertainments, among the means employed there, as in asylums on this side the Atlantic.

The following are the only tables which we have been able to construct from the statistical observations contained in these various reports. The deficiencies under this head constitute a very great defect in the majority of the reports. Much light might be thrown upon many points in the history of insanity, if the materials placed at the disposal of the medical officers of asylums were not permitted to be entirely lost: this we are compelled to say is the case in most of the reports now before us. The omissions will be evident from a glance at the tables which we have drawn up, particularly with reference to the forms of the disease, its causes, duration, pathological appearances, influence of rank, occupation, &c. &c.

We have in hand several other Reports of Asylums for the current year. We shall notice these in a separate article.

Familiar Views of Lunacy and Lunatic Life; with Hints on the Personal Care and Management of those who are afflicted with temporary or permanent Mental Derangement. By the late Superintendent of an Asylum for the Insane. Small 8vo. pp. 195. London: Parker. 1850.

This volume is addressed to the general reader, the author supposing "that a work in which all medical and other offensive detail should be entirely

omitted, might find favour with such readers as wish to indulge a rational curiosity regarding the past and present state of knowledge on the subject of intellectual disorder, and the institutions and remedies which have from time to time been adapted to the purpose of its amendment, and yet are unprepared to encounter reports and session-papers, or prohibited the use of such books as are too exclusively of a professional character."

* Out of 1899 patients.

† The immediate cause of death is specified in these four only among the reports.

We should have judged the subject to be one certainly difficult to popularise, and that the work in which it is thus brought to the level of the comprehension of the general reader must necessarily have but a limited circulation; that is to say, that it will be confined to the perusal of those who may unfortunately become directly concerned with mental disease in their families or friends. To this class of readers the volume before us affords much useful instruction, and conveys some judicious advice; while to others not so immediately interested in the subject, it will at the same time furnish much interesting historical information.

Proceedings of Societies.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Edinburgh, August 1.

Some Observations on the Growth of Plants in Abnormal Atmospheres. By DR. J. H. GLADSTONE and MR. G. GLAD- STONE.

ACCORDING to the authors of this paper, while oxygen is the most important constituent of the atmosphere, so far as animal life is concerned, it is upon the carbonic acid, ammonia, and aqueous vapour that the vegetable world is supremely dependent. The question arises, Do the oxygen and nitrogen of the air play no important part in the process of vegetation? The following preliminary experiments, with a view to the solution of this and similar inquiries, were detailed by the authors:—A pansy lived for the length of twenty-four days in an atmosphere of hydrogen, containing 5 per cent. of carbonic acid; one similarly placed in an atmosphere of common air remained healthy for a longer period. Five onions, just commencing to sprout, were severally placed in carbonic acid, carbonic oxide, coal-gas, air containing 8 per cent. of light carburetted hydrogen, and ordinary atmospheric air. The germination of the first two was entirely stopped, while the hydrocarbons appeared considerably to accelerate the growth of the vegetable. The plants in each instance lost weight. A pansy in flower, a young stock, and a grass plant, were placed in pure nitrogen gas. The former two soon died; but the grass was

still growing a month after the commencement of the experiment. Another pansy was placed in a mixture of oxygen and hydrogen gases in the proportions requisite to form water. In order to imitate the balance that obtains in nature between animal and vegetable life, some flies were introduced, along with some sugar, to serve as their food. The experiment was commenced a fortnight since, and the plant, when last observed, was in good condition. Owing to the low specific gravity of the mixed gases, the flies were unable to mount on the wing, or make the usual buzzing noise; but the substitution of hydrogen for nitrogen in the atmosphere had no marked effect upon their breathing; thus confirming the observations of M. Regnault by an instance drawn from the Articulate.

On the Air and Water in Towns, and the Action of Pansy Strata on Water and Organic Matter. By DR. R. A. SMITH.

IT is a matter of great importance to find from what source it is best to obtain water for large towns, and how it is to be collected. To these points Dr. Smith particularly directs attention. Regarding the conditions of many springs, which never become muddy, but possess a constant brilliancy and a very equal temperature at all seasons of the year, the author thinks that there is a purifying and cooling action going on beneath. The surface water from the same place, even if filtered, has not the same brilliancy; it has not the same freedom from organic matter, neither is it equally charged with carbonic acid or oxygen gas: there are other influences, therefore, at work. The rain which falls has not the purity, although it comes directly from the clouds; it may even be wanting in cleanness, as is often the case. Springs rise through a great extent of soil, and collect a considerable amount of inorganic salts; and it is shown by Dr. Smith that their purity is due entirely to the power of the soil to separate all organic matter, and at the same time to compel the mixture of carbonic acid and oxygen. The amount of organic matter removed in this way is surprising, and it is a most important and valuable property of the soil. The change even takes place close to cesspools and sewers: at a very short distance from the most offensive organic matter there may be found water having little or none in it. As an agent for purifying towns, this oxidation of organic matter is the most extraordinary, and we find the soil of towns which have been inhabited for centuries still possessing this remarkable power. St. Paul's Churchyard may be looked upon as one of the oldest parts of London; and the water from the wells around it is remark-

ably pure, and the drainage of the soil is such that there is very little, if any, salts of nitric acid in it. If the soil, says Dr. Smith, has such a power to decompose by oxidation, we want to know how it gets so much of its oxygen. We must, however, look to the air as the only source, and see how it can come from it. When water becomes deprived of oxygen, it very soon takes it up again, as may be proved by experiment. This shows us that, as fast as the oxygen is consumed by the organic matter, it receives a fresh portion, conveyed to it by the porous soil. Several experiments of the following character were given, to show the filtering power of the soil:—A solution of peaty matter was made in ammonia: the solution was very dark, so that some colour was perceived through a film of only the twentieth of an inch in thickness. This was filtered through sand, and came out perfectly clear and colourless. Organic matter dissolved in oil of vitriol was separated from it by a thickness of stratum of only four inches. A bottle of porter was by the same process deprived of all its colour. The material of which this filter is made is of little importance,—one of the best, according to Dr. Smith, as far as clearing the water is concerned, being of steel filings; oxide of iron, oxide of manganese, and powdered bricks all answering equally well. This shows that the separation of the organic matter is due to some peculiar attraction of the surfaces of the porous mass presented to the fluid. This paper was a continuation of Dr. Smith's report published last year, and he purposes continuing the inquiry.

On the relative values of the Dietsaries in use by different classes of the Population.
By DR. LYON PLAYFAIR.

DR. PLAYFAIR has been engaged for some time in an examination of the dietaries adopted in the union houses, schools, and other great establishments in this country, the object of the inquiry being the determination of the most nutritious diet. The result of this inquiry has proved that no system of any value has been adopted by any of the boards controlling our national schools and charities; and hence the high importance is shown of some accurate examination—such as that brought forward by Dr. Playfair—of the value, chemically and physiologically, of the dietaries adopted.

The reading of this paper gave rise to a discussion as to the merits of the hypothesis upon which the reductions of these dietary tables have been made; and it was argued that we had no distinct evidence to prove that nitrogen alone fairly represents the amount of nutrition contained in an article of diet.

On the Climate of the Valley of the Nile.
By MR. T. SPENCER WELLS, R.N.

THE observations extend from the 6th of December, 1840, to the 16th of March, 1850. The instruments were kept in a cabin in the boat of an invalid. The cabin was six feet high, twelve feet broad, and ten feet deep. Its floor was from one to two feet above the level of the river. The dry and wet bulb thermometers, and the barometer, were fixed to a beam in the centre of the cabin, where they were not exposed either to the direct or reflected rays of the sun. There were six glass windows to the cabin, provided with open blinds. Some of these windows were always open during the day, so that the morning and afternoon observations may be considered to represent the temperature of the open air in the shade. Sometimes a window was open until after the evening observations, but more frequently this was not the case; and to this I ascribe the fact, that the mean of the evening observations is above that of the morning. A register night thermometer was fixed outside one of the windows, and the lowest temperature observed each day is recorded. These daily observations were made at the hours of 9 A.M., 3 P.M., and 11 P.M.; and an abstract of these daily observations was exhibited.

The mean temperature of the air for the period of my observations at Greenwich was $39^{\circ} 3'$; on the Nile it was 61° . Thus there was a difference of 22 degrees in the mean temperature of Egypt over that of Greenwich during these months.

The mean temperature of evaporation at Greenwich was $37^{\circ} 4'$, in Egypt 55° ; being 18 degrees above the mean at Greenwich for the same period.

The mean temperature of the dew point at Greenwich was $84^{\circ} 1'$, in Egypt $50^{\circ} 8'$. Thus in England the air was saturated by the quantity of vapour contained in it at a temperature 16 degrees below that at which saturation occurred in Egypt.

The mean elastic force of vapour in Egypt was 0.384, at Greenwich 0.214. In other words, the pressure of the watery vapour mixed with the air was capable of supporting a column of mercury higher by $\frac{1}{10}$ of an inch in Egypt than in England.

The mean weight of water in a cubic foot of air in England was 3 grains, in Egypt 4 grains and $\frac{1}{10}$; but still, owing to the higher temperature, the air was much drier in Egypt. When the temperature of the air is considerably above that of the dew point, the air is dry, dissolving or absorbing aqueous vapour without any tendency to precipitation in the form of rain, and it is dry in proportion to the difference between the two temperatures. Thus, although the mean weight of water in a cubic

foot of air was greater last winter in Egypt than in England, yet the air was much more nearly saturated with moisture in England than in Egypt. At Greenwich the mean additional weight of water required to saturate a cubic foot of air was only $\frac{1}{10}$ of a grain, while on the Nile it was 1 grain and $\frac{3}{4}$. If we represent air completely deprived of moisture by zero, and air completely saturated as unity, the mean degree of humidity on the Nile was 75 per cent., while at Greenwich it was 85 per cent.

The mean readings of the barometer in the two countries very nearly approach each other; in Egypt being 29.99, at Greenwich 29.87. A glance at the table, however, showed how very small the extreme range of the instrument was on the Nile.

The average weight of a cubic foot of air at Greenwich was 549 grains, in Egypt 527 grains.

Rain fell in various districts of England on averages from 31 to 61 days, while in Egypt it only fell on 5 days, and on three of these a shower was of but a few minutes' duration. On two days rain fell heavily at Cairo for several hours.

The mean daily range of the temperature of the air at Greenwich was 11.37, in Egypt 10.31: but, while the mean extreme range in Egypt was 38, at Greenwich it was but 29; the mean extreme range in the cabin being only 7 degrees below that on the grass at Greenwich in the open air.

Fog was occasionally, but rarely, observed. It was general in the Delta in the early morning; but above Cairo was only observed on three occasions.

ACADEMY OF MEDICINE, PARIS.

Aug. 20, 1850.

Accident from Chloroform.

M. DELABUE stated, that having occasion to make extensive incisions in the thigh of a woman, in order to lay open some fistulous tracts, he had previously administered five grammes (= 75 grains) of chloroform on a sponge, during five minutes. When about to operate he noticed the patient's head fall towards her right shoulder, her body incline forwards, and a sanguinolent froth issue from her mouth, respiration and pulse being scarcely detectable. By repeated slaps on the chest, cold water applied to the head, sinapisms to the feet, and irritation of the fauces, movements of the eyelids were produced, followed by free vomiting. After complete restoration, a haggard look of the eye and extreme loquacity continued for about a quarter of an hour.

Iodated Oil a Substitute for Cod-liver Oil.

M. PERSONNE observed that, as the medicinal properties of cod-liver oil depend upon a combination of iodine and fatty matter, it had appeared to him more rational to employ an oil so prepared as to contain always a known quantity of iodine, in an uniform state of combination.

Black Discolouration of the Countenance.

M. BOUSQUET related two cases, one of which consisted of a form of purpura hæmorrhagica; in the second, a blue tint appeared about the eyelids, ears, and neck, which could be washed off, but returned after a time. The blue tint subsequently changed to black. This patient had been the subject of a convulsive cough, which had disappeared and been replaced, simultaneously with the appearance of the discolouration, by a severe headache. The latter case was regarded as analogous to the instances that are recorded of sanguineous perspiration.

SURGICAL SOCIETY OF PARIS.

Aug. 21, 1850.

MR. COLSON transmitted to the Society a voluminous memoir on the malformations of the anus and rectum. The secretary was requested to prepare an analysis of this work.

Double Lachrymal Tumor.

M. AUZIAS-TURENNE gave a description of the pathological changes observed in the dissection of a case of double lachrymal tumor. The lachrymal orifices and ducts were free from disease, but considerable thickening of the mucous membrane of the sac was observed. The nasal canal was free at its upper part, but was completely obliterated below. The seat of the obstruction had presented an obstacle to a cure.

ON THE EMPLOYMENT OF NITRATE OF SILVER IN INFANTILE ENTERITIS.

M. DUCLOS has found the nitrate of silver, administered in enemata, serviceable in acute or chronic colitis in very young infants, and its administration unattended with danger. It is equally beneficial in acute or chronic dysentery. Administered by the mouth and in enemata at the same time, it has exercised a favourable influence on the vomiting and diarrhoea of choleraic enteritis of infants. In short, M. Duclos states that he has obtained the best results from the exhibition of this medicine in acute inflammation of the mucous membrane throughout the whole length of the alimentary canal.—*L'Union Médicale*. x

Hospital and Infirmary Reports.

FELLOWS' PRIZE ESSAY.

Summer Session 1845.

By C. H. F. ROUTE, M.D. Lond.

QUESTION PROPOSED—*Are There any conditions, and if so, what are they, in which an excess of urea is contained in*

the whole quantity of urine passed in 24 hours?

PART I.—The answer of the above question depends essentially upon that of the two following.

1st. What is the average density and quantity of urine excreted in health, taking the whole quantity passed in 24 hours? 2nd. What is the normal proportion of urea contained in this quantity of urine?

1st. In relation to the quantity and density of urine in the normal state, it is remarkable what a discrepancy exists amongst authors. [This will be at once obvious by reference to the subjoined table.

	Sp. gr.		No. of oz. passed in 24 hours.
Dr. Thomson	1010		
" Prout	1020		80 to 40
" Willis	1010 children	1015 adults	
" Venables	1012 to 1017		
" McGregor	1017		
" Christison	1029		30 to 50
" J. Gregory Secundus	1025		
" Golding Bird			20 to 48
" Becquerel	1018 men	1015 women	17 to 73
" Lecana	1025		19 to 47
" Rayer			21 to 57

And yet these averages may, after all, be quite correct. For, without doubt, in health the urine is liable to great variations. First, it will vary usually in density according to the time of the day in which it has been passed: hence the divisions into *urine potus*, *sanguinis*, and *chylis*. Then the quantity will be increased by the amount of fluid drunk,—frequently by the diuretic effect of medicines or mental emotions,—by disease, as in certain varieties of diabetes. So other diseases and medicines may have an opposite effect. The same causes will also affect its density. Some alcoholic liquors highly nutritious, and especially animal or azotized food, will raise the density. Low diet, and vegetable diet, will lower it. It is to most of these contingencies, therefore, that we must ascribe the discrepancy before remarked.

It is not purposed, therefore, to enter into a controversy as to which of the above-named authors is most correct. These opinions, if questioned at all, will only be canvassed where this is necessary to justify our own, if opposite conclusions: for we cannot admit the correctness of Dr. Christison's opinion (*Library of Med.*), who states "that the determination of the characters of average healthy urine is of little value in physiology, and of no importance in relation to medical practice." On the contrary, we believe that to do this is of paramount importance, as, by the very

means of comparison it holds out, it often enables us, in many instances, to diagnose renal or other disease, where other morbid symptoms are either entirely absent, or doubtful in kind. The truth of this assertion we trust has been already shown in the Fellows' Cases already published.

The average given by Dr. Christison is valuable as an example of the high density to which, even in ordinary instances, the urine of a healthy man may attain. The case was that of an ordinary male in the middle ranks of life, and enjoying ordinary diet,—i. e. from 24 to 30 oz. of solid food daily; rather sparing in the use of liquids, and abstaining for the time from wine and the stronger alcoholic liquors. This man used to pass about 35 oz. of urine, of a sp. gr. of 1029, in the 24 hours; and this average was taken from the whole quantity of urine passed in 7 continuous days. Dr. J. Gregory gives, as the extremes for adult and middle age, 1005 and 1033. The greatest range for the same individual, 21°. The ordinary range between 1816 and 1031, and the mean of 363 experiments on 50 individuals, 1022.5. Remark upon these experiments (*Lib. of Med.*), Dr. Christison states that this average is rather low than high, because he knows that many of the experiments were made soon after breakfast, and comparatively few after dinner; and accordingly the average of 5 individuals whose urine was tried between 20

and 50 times each, was 1025.2; and this last number he supposes would indicate the average.

There appears, however, to us to be another objection to make to this conclusion. To take an average density from specimens collected at different times of the day, and that even when the parties voiding them are under the same circumstances of diet, so that the urines generally must have the same character, is unsafe; for it is found, by actual experiment, that urines so selected

are of very different specific gravities. It has been too generally supposed that the morning urine is usually of a higher specific gravity than the evening. This, doubtless, is often the case, but it is by no means even the general rule. This may be shown by the following table of densities indifferently selected out of several hundred cases, with a view to determine this point. The cases occurred in University College Hospital.

1st. When the morning urine was highest.

No.	Name.	Sp. g. A.M.	Sp. g. P.M.	No.	Name.	Sp. g. A.M.	Sp. g. P.M.	Mean.
1	G. Jones 1.	1023	1020	8	Federmann	1030	1025	A.M. 1023. P.M. 1018.2.
2	Body . .	1021	1016	9	Bell . . .	1025	1019	
3	Dunn . .	1026	1023	10	G. Jones 2.	1035	1030	
4	Plummer .	1020	1010	11	Green . .	1018	1015	
5	Whitehead.	1020	1017	12	Nicholson .	1018	1011	
6	Knight . .	1021	1010	13	Griffiths .	1021	1019	
7	Lee . . .	1033	1030	14	Collier . .	1012	1010	

2nd. When the evening urine was highest.

No.	Name.	Sp. g. A.M.	Sp. g. P.M.	No.	Name.	Sp. g. A.M.	Sp. g. P.M.	Mean.
1	G. Jones 1.	1018	1024	8	Plummer .	1012	1024	A.M. 1021.0. P.M. 1026.7.
2	Stockley .	1020	1026	9	Lee . . .	1024	1031	
3	G. Jones 1.	1018	1023	10	Hill . . .	1018	1027	
4	G. Jones 2.	1023	1033	11	Nicholson .	1023	1027	
5	Plummer .	1021	1024	12	Collins . .	1013	1015	
6	Hayden . .	1028	1031	13	G. Jones 2.	1027	1032	
7	Taylor . .	1028	1031					

Sometimes, however, it should be admitted that the morning and evening urine have the same specific gravity: in twelve cases so collected the average sp. gr. was 1024.6.

Bequerel fixes the specific gravity of healthy urine at 1017; men, 1018; women, 1015. This opinion appears to have been deduced from well-founded experiments. But all our English writers appear to have overlooked one source of fallacy in these averages, as applied to the English. The latter live higher, more exclusively on animal and alcoholic liquors. Moreover, *without any doubt*, the English Hospital diet is far superior to that given in the French Hospitals: necessarily, therefore, the sp. gr. of the urine of the English will be higher, on the average, than that of the French.

Dr. G. Bird, with a view of obtaining the sp. gr. of urine of 24 hours, recommends, where the sample itself of the 24 hours cannot be obtained, the collection of a specimen of the *urina hyali*, or that passed immediately before going to bed, as also of a specimen of the *urina sanguinis*, or that passed in the morning, to be taken,—the

average specific gravity of these two specimens giving a near approach to the sp. gr. of a specimen of the whole urine passed in 24 hours. This is doubtless true, or very nearly so, for many cases. It is also true for the mean of a large number of cases: but it is sometimes very incorrect for a large number of individual cases.

Before, however, proving this assertion by figures, it may be well to explain the manner in which we operated on the specimens of urine ourselves.

One of the chief difficulties we had to contend with was the obtaining samples of the whole quantity of urine passed in a period of 24 hours.

1st. To confide in the statements made by the patients themselves is often very fallacious. Some wilfully deceive, and others fancy they have made a good deal of water, because, in consequence of some ardor *urinae* present,—an enlarged prostate or other cause,—*they frequently micturate*; while in reality the quantity passed each time has been so small that the absolute quantity passed in the 24 hours is deficient.

2nd. When patients are labouring under

acute attacks, purgatives are commonly administered; and thus, passing most of their urine with their motions, they neither will nor can save the whole quantity of urine passed in 24 hours; besides, with females the presence of the catamenia is often another impediment.

3rd. Most patients have a natural disinclination to save the urine passed, from a natural feeling of delicacy, and require to be closely watched not to deceive in this respect. This objection applies especially to females. In No. 3 ward (female ward), this could never be effected; and at the most the measure was given in pints and half-pints. In the other wards

more facilities were afforded. The whole quantity here was saved and measured. In No. 4 ward, however, it was that we collected our more important data. Here the head nurse not only caused the whole quantity of the urine to be saved and measured, but the whole quantity of that passed in the morning, in the evening, and during the whole day, was always separately measured, and not trusted to memory, but carefully recorded on a slate, and separate samples of each set aside for examination. These experiments are therefore to be entirely relied upon.

The following table of examples indiscriminately selected from a large number

No.	Name.	Sp. gr. A.M.	Sp. gr. P.M.	Sp. gr. mean, by calculation.	Sp. gr. of 24 hours' urine by actual experiments

38	G. Jones 1	1016	1021	1018.5	1021
39	Whitehead	1007	1010	1008.5	1010
40	Knight	1031	1031	1031	1032
41	Do.	1031.8	1008	1019.5	1011
42	Hill	1016	1027	1022.5	1025
43	Taylor	1028	1031	1029.5	1031
44	Mean	1023.6	1023.2	1023.4	1024.1

of cases, will serve to show that the mean density of morning and evening urine is not always the same as that of a sample of the whole quantity of urine passed in a period of 24 hours, though it is almost time for the average mean.

The explanation seems to be, that, when the density is high, a less quantity of urine is passed at the time, though even this is not invariably the case.

In endeavouring, therefore, to select an average specific gravity and density, we have adopted another plan—the only one, indeed, open to us. We took the average quantity and density of a number of convalescent patients at the hospital, in whom no certain indication of renal disease, especially Bright's, could be traced, their diet being at the time full or extra full. Thus a series of numbers were obtained, and the means obtained looked upon as the average densities of healthy urine.

In this manner eighteen examples were collected; each we divided into two series,—the first where the quantity of urine passed did not exceed 36 ounces,—the second where it did.

The following table is useful for reference, and will further explain the value of these numbers: it is based upon Dr. Day's table, only giving the quantity of solid matter contained in each ounce.

Sp. gr.	Solid matter in 1 oz.	Sp. gr.	Solid matter in 1 oz.	Sp. gr.	Solid matter in 1 oz.
1000	0	1014	15.87	1028	32.19
1001	1.11	1015	17.02	1029	33.37
1002	2.24	1016	18.18	1030	34.55
1003	3.36	1017	19.33	1031	35.76
1004	4.53	1018	20.29	1032	36.93
1005	5.61	1019	21.60	1033	37.72
1006	6.75	1020	22.81	1034	39.79
1007	7.88	1021	23.97	1035	40.51
1008	9.01	1022	25.84	1036	41.71
1009	10.00	1023	26.84	1037	42.91
1010	11.19	1024	27.88	1038	44.06
1011	12.43	1025	29.13	1039	44.48
1012	13.62	1026	29.83	1040	46.52
1013	14.72	1027	31.41		

Applying this table to the numbers above given, we have:—

Solid matters excreted in 24 hours.
grains.

Average for the whole 18 cases . . . 813.12
 " first 13 . . . 748.86
 " last 5 . . . 980.16
 " 2d, 5th, and 13th 1107.3
 " 14th, 16th, & 17th 1120.5
 " Dr. Christison's case 1167.9

These numbers represent nearly enough the limits of health. If due attention be, moreover, paid to the amount of ingesta taken,—and supposing it in all cases to have been sufficient in quantity,—it will afford an easy means very often of diagnosing renal disease where other symptoms are doubtful or obscure.

The same method of calculation cannot be applied to the case where we are seeking to find out the quantity of urea contained in a given quantity of urine. From Berzelius's analysis it would appear that in healthy urine the proportion of urea to the total amount of solid matter contained in the urine is as 1 to 2.23. Becquerel gives for males 1 to 2.43, females 1 to 2.49. These proportions, however, though apparently not very different one from another, are in reality very much so; as Christison makes the amount of solids in 1000 grains equal to the difference between 1000 and its density multiplied by 2.33, whereas Becquerel makes it equal to the difference between 1000 and its density multiplied by 1.65.

Again, urines of the same specific gravity are found by experiment to contain very different quantities of urea. Take,

for instance, the following examples:—Becquerel found, in four experiments made upon urines of sp. gr. 1023, the following quantities of urea:—13·06, 10·72, 11·98, and 16·88. We ourselves, in three specimens of urine of sp. gr. 1026, 21·00, 20·64, and 16·00. This difference arises, in many instances, from the quantity of colouring matter contained in the urine. It is for this reason that Becquerel has attempted a division of urine into five varieties:—

1st. Cases in which the urine is very high coloured, of high specific gravity, very acid, and in general deficient in quantity. In these cases there is always more or less febrile movement, or some acute attack present.

2d. Cases in which the urine is pale, clear, of low specific gravity, little or not at all diminished in quantity, and in general passed by weak and anæmic persons.

3d. Cases in which the urine is dark, sufficiently changed, diminished in quantity, as in the first series, but with low specific gravity. This variety is usually passed by individuals weakened by the nature of disease present, or remedies given, differing, however, from the first series, inasmuch as there is febrile movement and functional disease.

4th. Analogous cases to the preceding, in which the amount of watery portions is less considerable.

5th. These cases differ little in appearance from those of the healthy urine. The patients are generally free from disease, but not affected with febrile or functional disorder.

The averages resulting from this arrangement may be expressed in the following table.—(See first table on next page.)

This arrangement, however nice, is yet too complicated for general application. In the first place, as a *general rule*, all urines of a pale colour are of a low specific gravity; whereas those of a dark have a high density. These two, therefore, belong to the same scale, the pale at the beginning, the dark at the end.

In the third and fourth series the cases are analogous to the two former, only there is more colouring matter; while in the fifth the approach is too near the normal state to require a separate division.

It is, however, sometimes of advantage to be able to know at once, even though only approximatively, the quantity of urea excreted in 24 hours. In order to effect this, we have adopted the following arrangement:—We make four divisions in the varieties of urine.

The first division includes the first and second series of Becquerel, and may be considered as subdivided into two parts—the first subdivision, in which the urine has a specific gravity not above 1015, are

also pale and clear, generally voided by anæmic and debilitated persons. The second subdivision, the urine of a specific gravity above 1015, frequently turbid from the presence of lithates, and voided by persons of a plethoric habit, or who are labouring under some febrile attack.

As opposed to these are what may be considered the extremes of both subdivisions; the first with an increase of colouring matter and less urea, the other with more urea and less colouring matter: while, lastly, we have affixed a table of what appears to be healthy urine, and as the quantity of urea would be affected by the quantity of liquid drunk being small or very great, in a healthy and well fed person.

This table has been brought out by a

Sp. gr.	Healthy urine.	Diseased urines.		
		1.	Coloured 2.	3.
1000	0	0	—	—
1001	·30	·26	—	—
1002	·61	·52	—	—
1003	·91	·79	—	—
1004	1·23	1·04	—	—
1005	1·64	1·44	·78	1·87
1006	2·06	1·78	·97	2·29
1007	2·48	2·08	1·15	2·71
1008	2·88	2·38	1·34	3·14

1019	6·94	5·90	3·28	7·62
1020	7·24	6·28	3·42	7·96
1021	7·54	6·72	3·64	8·57
1022	7·84	7·10	3·86	9·08
1023	8·32	7·49	4·09	9·59
1024	8·89	7·88	4·31	10·00
1025	9·47	8·30	4·53	10·52
1026	10·05	8·64	—	11·00
1027	10·63	9·05	—	11·48
1028	11·13	9·42	—	11·96
1029	11·64	9·81	—	12·44
1030	12·15	10·18	—	12·92
1031	12·61	10·57	—	13·39
1032	13·09	10·96	—	13·87
1033	13·56	11·36	—	14·34
1034	13·92	11·69	—	14·83
1035	14·28	12·08	—	15·30
1036	14·64	12·41	—	15·72
1037	15·01	12·70	—	16·12
1038	15·37	13·08	—	16·54
1039	15·73	13·43	—	16·96
1040	16·10	13·76	—	17·43

series of calculations too tedious to be enumerated, but founded on Becquerel's and our own analyses of healthy and dis-

eased urines; the two, when reduced to a common unit, being found generally to agree very well.

[Table referred to in preceding page.]

	Sp. gr.	No. of oz. in 24 hours.	Urea in 1 oz. grains.	Urea to 1000 parts urine. grains.
1st series, founded on 11 cases	1021.9	19.7	4.16	9.00
2d " " 11 "	1011.8	35.1	3.37	7.03
3d " " 7 "	1014.8	18.4	2.36	4.91
4th " " 5 "	1010.5	40.1	4.27	8.91
5th " " 3 "	1017.7	30.3	5.93	12.35

The largest and smallest quantity of urea upon the average is stated by Becquerel to be in health—

	Sp. gr.	Grains in 1 oz.	Whole quantity excreted in 24 hours.
Males	1018.9	6.64	260.81
Females	1015.1	4.97	255.53
Mean	1017.01	5.80	258.17

Whence he infers that the normal quantities vary usually from 4.80 to 6.72 grains for every ounce of urine, and the quantity excreted in 24 hours varies from 231.60 to 277.92.

These numbers do not quite agree with those obtained by Lecanu from a total of 126 cases: he found that the quantity of urea voided was in 24 hours—

	Minimum. Grains.	Mean. Grains.	Maximum. Grains.
By men	357.33	433.81	510.29
" women	147.66	292.31	436.95
" old men (84 to 86)	60.98	178.01	295.05
" children 8 years	162.64	208.31	254.14
" " 4 years	57.28	69.50	81.10

The experiment, moreover, of Lehmann, of Leipsic, showed that in his case he could greatly increase the urea by animal diet, so as to exceed Lecanu's average:—

	Urea in 24 hours.
By animal diet	819.2
